CHAPTER 1

BACKGROUND

1.1. Introduction

Formally, Polkadot is a replicated sharded state machine designed to resolve the scalability and interoperability among blockchains. In Polkadot vocabulary, shards are called *parachains* and Polkadot *relay chain* is part of the protocol ensuring global consensus among all the parachains. The Polkadot relay chain protocol, henceforward called *Polkadot protocol*, can itself be considered as a replicated state machine on its own. As such, the protocol can be specified by identifying the state machine and the replication strategy.

From a more technical point of view, the Polkadot protocol has been divided into two parts, the *Runtime* and the *Runtime environment* (RE). The Runtime comprises most of the state transition logic for the Polkadot protocol and is designed and expected to be upgradable as part of the state transition process. The Runtime environment consists of parts of the protocol, shared mostly among peer-to-peer decentralized cryptographically-secured transaction systems, i.e. blockchains whose consensus system is based on the proof-of-stake. The RE is planned to be stable and static for the lifetime duration of the Polkadot protocol.

With the current document, we aim to specify the RE part of the Polkadot protocol as a replicated state machine. After defining the basic terms in Chapter 1, we proceed to specify the representation of a valid state of the Protocol in Chapter 2. In Chapter 3, we identify the protocol states, by explain the Polkadot state transition and discussing the detail based on which Polkadot RE interacts with the state transition function, i.e. Runtime. Following, we specify the input messages triggering the state transition and the system behaviour. In Chapter 5, we specify the consensus protocol, which is responsible for keeping all the replica in the same state. Finally, the initial state of the machine is identified and discussed in Appendix C. A Polkadot RE implementation which conforms with this part of the specification should successfully be able to sync its states with the Polkadot network.

1.2. Definitions and Conventions

DEFINITION 1.1. A Discrete State Machine (DSM) is a state transition system whose set of states and set of transitions are countable and admits a starting state. Formally, it is a tuple of

$$(\Sigma, S, s_0, \delta)$$

where

- Σ is the countable set of all possible transactions.
- S is a countable set of all possible states.
- $s_0 \in S$ is the initial state.
- δ is the state-transition function, known as **Runtime** in the Polkadot vocabulary, such that

$$\delta: S \times \Sigma \to S$$

8 Background

DEFINITION 1.2. A path graph or a path of n nodes formally referred to as P_n , is a tree with two nodes of vertex degree 1 and the other n-2 nodes of vertex degree 2. Therefore, P_n can be represented by sequences of $(v_1, ..., v_n)$ where $e_i = (v_i, v_{i+1})$ for $1 \le i \le n-1$ is the edge which connect v_i and v_{i+1} .

Definition 1.3. Radix-r tree is a variant of a trie in which:

- Every node has at most r children where $r = 2^x$ for some x;
- Each node that is the only child of a parent, which does not represent a valid key is merged with its parent.

As a result, in a radix tree, any path whose interior vertices all have only one child and does not represent a valid key in the data set, is compressed into a single edge. This improves space efficiency when the key space is sparse.

DEFINITION 1.4. By a sequences of bytes or a byte array, b, of length n, we refer to

$$b := (b_0, b_1, ..., b_{n-1})$$
 such that $0 \le b_i \le 255$

We define \mathbb{B}_n to be the **set** of all byte arrays of length n. Furthermore, we define:

$$\mathbb{B} := \bigcup_{i=0}^{\infty} \, \mathbb{B}_i$$

Notation 1.5. We represent the concatenation of byte arrays $a := (a_0, ..., a_n)$ and $b := (b_0, ..., b_m)$ by:

$$a || b := (a_0, ..., a_n, b_0, ..., b_m)$$

Definition 1.6. For a given byte b the bitwise representation of b is defined as

$$b := b^7 \dots b^0$$

where

$$b = 2^0 b^0 + 2^1 b^1 + \dots + 2^7 b^7$$

DEFINITION 1.7. By the little-endian representation of a non-negative integer, I, represented as

$$I = (B_n ... B_0)_{256}$$

in base 256, we refer to a byte array $B = (b_0, b_1, ..., b_n)$ such that

$$b_i := B_i$$

Accordingly, define the function EncLE:

Enc_{LE}:
$$\mathbb{Z}^+$$
 $\rightarrow \mathbb{B}$ $(B_n...B_0)_{256} \mapsto (B_0,B_1,...,B_n)$

DEFINITION 1.8. By **UINT32** we refer to a non-negative integer stored in a byte array of length 4 using little-endian encoding format.

DEFINITION 1.9. A **blockchain** C is a directed path graph. Each node of the graph is called **Block** and indicated by B. The unique sink of C is called **Genesis Block**, and the source is called the **Head** of C. For any vertex (B_1, B_2) where $B_1 \rightarrow B_2$ we say B_2 is the **parent** of B_1 and we indicate it by

$$B_2 := P(B_1)$$

X

DEFINITION 1.10. By UNIX time, we refer to the unsigned, little-endian encoded 64-bit integer which stores the number of milliseconds that have elapsed since the Unix epoch, that is the time 00:00:00 UTC on 1 January 1970, minus leap seconds. Leap seconds are ignored, and every day is treated as if it contained exactly 86400 seconds.

1.2.1. Block Tree

In the course of formation of a (distributed) blockchain, it is possible that the chain forks into multiple subchains in various block positions. We refer to this structure as a *block tree*:

DEFINITION 1.11. The **block tree** of a blockchain, denoted by BT is the union of all different versions of the blockchain observed by all the nodes in the system such as every such block is a node in the graph and B_1 is connected to B_2 if B_1 is a parent of B_2 .

When a block in the block tree gets finalized, there is an opportunity to prune the block tree to free up resources into branches of blocks that do not contain all of the finalized blocks or those that can never be finalized in the blockchain. For a definition of finality, see Section 5.2.

DEFINITION 1.12. By **Pruned Block Tree**, denoted by PBT, we refer to a subtree of the block tree obtained by eliminating all branches which do not contain the most recent finalized blocks, as defined in Definition 5.26. By **pruning**, we refer to the procedure of BT \leftarrow PBT. When there is no risk of ambiguity and is safe to prune BT, we use BT to refer to PBT.

Definition 1.13 gives the means to highlight various branches of the block tree.

DEFINITION 1.13. Let G be the root of the block tree and B be one of its nodes. By **CHAIN**(B), we refer to the path graph from G to B in (P)BT. Conversely, for a chain C=CHAIN(B), we define **the head of** C to be B, formally noted as B := HEAD(C). We define |C|, the length of C as a path graph. If B' is another node on CHAIN(B), then by SUBCHAIN(B', B) we refer to the subgraph of CHAIN(B) path graph which contains both B and B'. Accordingly, $\mathbb{C}_{B'}((P)BT)$ is the set of all subchains of (P)BT rooted at B'. The set of all chains of (P)BT, $\mathbb{C}_{G}((P)BT)$ is denoted by $\mathbb{C}((P)BT)$ or simply \mathbb{C} , for the sake of brevity.

DEFINITION 1.14. We define the following complete order over \mathbb{C} such that for $C_1, C_2 \in \mathbb{C}$ if $|C_1| \neq |C_2|$ we say $|C_1| > |C_2|$ if and only if $|C_1| > |C_2|$.

If $|C_1| = |C_2|$ we say $C_1 > C_2$ if and only if the block arrival time of $\text{Head}(C_1)$ is less than the block arrival time of $\text{Head}(C_2)$ as defined in Definition 5.8. We define the $\text{Longest-Chain}(\mathbf{BT})$ to be the maximum chain given by this order.

DEFINITION 1.15. LONGEST-PATH(BT) returns the path graph of (P)BT which is the longest among all paths in (P)BT and has the earliest block arrival time as defined in Definition 5.8. DEEPEST-LEAF(BT) returns the head of Longest-Path(BT) chain.

10 Background

Because every block in the blockchain contains a reference to its parent, it is easy to see that the block tree is de facto a tree. A block tree naturally imposes partial order relationships on the blocks as follows:

Definition 1.16. We say B is descendant of B', formally noted as B > B' if B is a descendant of B' in the block tree.

CHAPTER 2

STATE SPECIFICATION

2.1. STATE STORAGE AND STORAGE TRIE

For storing the state of the system, Polkadot RE implements a hash table storage where the keys are used to access each data entry. There is no assumption either on the size of the key nor on the size of the data stored under them, besides the fact that they are byte arrays with specific upper limits on their length. The limit is imposed by the encoding algorithms to store the key and the value in the storage trie.

2.1.1. Accessing System Storage

Polkadot RE implements various functions to facilitate access to the system storage for the runtime. Section ? lists all of those functions. Here we formalize the access to the storage when it is being directly accessed by Polkadot RE (in contrast to Polkadot runtime).

DEFINITION 2.1. The **StoredValue** function retrieves the value stored under a specific key in the state storage and is formally defined as:

Stored
Value:
$$k \mapsto \left\{ \begin{array}{ll} \mathcal{K} \to \mathcal{V} \\ v & \textit{if } (k, v) \textit{ exists in state storage} \\ \phi & \textit{otherwise} \end{array} \right.$$

where $K \subset \mathbb{B}$ and $V \subset \mathbb{B}$ are respectively the set of all keys and values stored in the state storage.

2.1.2. The General Tree Structure

In order to ensure the integrity of the state of the system, the stored data needs to be re-arranged and hashed in a *modified Merkle Patricia Tree*, which hereafter we refer to as the *Trie*. This rearrangment is necessary to be able to compute the Merkle hash of the whole or part of the state storage, consistently and efficiently at any given time.

The Trie is used to compute the *state root*, H_r , (see Definition 3.5), whose purpose is to authenticate the validity of the state database. Thus, Polkadot RE follows a rigorous encoding algorithm to compute the values stored in the trie nodes to ensure that the computed Merkle hash, H_r , matches across the Polkadot RE implementations.

The Trie is a *radix-16* tree as defined in Definition 1.3. Each key value identifies a unique node in the tree. However, a node in a tree might or might not be associated with a key in the storage.

When traversing the Trie to a specific node, its key can be reconstructed by concatenating the subsequences of the key which are stored either explicitly in the nodes on the path or implicitly in their position as a child of their parent.

12 State Specification

To identify the node corresponding to a key value, k, first we need to encode k in a consistent with the Trie structure way. Because each node in the trie has at most 16 children, we represent the key as a sequence of 4-bit nibbles:

DEFINITION 2.2. For the purpose of labeling the branches of the Trie, the key k is encoded to $k_{\rm enc}$ using KeyEncode functions:

$$k_{\text{enc}} := (k_{\text{enc}_1}, \dots, k_{\text{enc}_{2n}}) := \text{KeyEncode}(k)$$

$$(2.1)$$

such that:

$$\text{KeyEncode}(k) : \begin{cases} \mathbb{B} & \to \text{ Nibbles}^4 \\ k := (b_1, ..., b_n) := & \mapsto & (b_1^1, b_1^2, b_2^1, b_2^1, ..., b_n^1, b_n^2) \\ & := (k_{\text{enc}_1}, ..., k_{\text{enc}_{2n}}) \end{cases}$$

where Nibble⁴ is the set of all nibbles of 4-bit arrays and b_i^1 and b_i^2 are 4-bit nibbles, which are the big endian representations of b_i :

$$(b_i^1, b_i^2) := (b_i/16, b_i \mod 16)$$

, where mod is the remainder and / is the integer division operators.

By looking at k_{enc} as a sequence of nibbles, one can walk the radix tree to reach the node identifying the storage value of k.

2.1.3. Trie Structure

In this subsection, we specify the structure of the nodes in the Trie as well as the Trie structure:

NOTATION 2.3. We refer to the set of the nodes of Polkadot state trie by \mathcal{N} . By $N \in \mathcal{N}$ to refer to an individual node in the trie.

DEFINITION 2.4. The State Trie is a radix-16 tree. Each Node in the Trie is identified with a unique key k_N such that:

- k_N is the shared prefix of the key of all the descendants of N in the Trie.

and, at least one of the following statements holds:

- (k_N, v) corresponds to an existing entry in the State Storage.
- N has more than one child.

Conversely, if (k, v) is an entry in the State Trie then there is a node $N \in \mathcal{N}$ such that $k_N = k$.

NOTATION 2.5. A branch node is a node which has one child or more. A branch node can have at most 16 children. A leaf node is a childless node. Accordingly:

$$\mathcal{N}_b := \{ N \in \mathcal{N} | N \text{ is a branch node} \}$$
$$\mathcal{N}_l := \{ N \in \mathcal{N} | N \text{ is a leaf node} \}$$

For each Node, part of k_N is built while the trie is traversed from root to N part of k_N is stored in N as formalized in Definition 2.6.

DEFINITION 2.6. For any $N \in \mathcal{N}$, its key k_N is divided into an **aggregated prefix key**, $\mathbf{pk_N^{Agr}}$, aggregated by Algorithm 2.1 and a **partial key**, $\mathbf{pk_N}$ of length $0 \le l_{\mathbf{pk_N}} \le 65535$ in nibbles such that:

$$pk_N := (k_{\text{enc}_i}, ..., k_{\text{enc}_{i+l_{pk_N}}})$$

where pk_N is a suffix subsequence of k_N ; i is the length of pk_N^{Agr} in nibbles and so we have:

$$\text{KeyEncode}(k_N) = \text{pk}_N^{\text{Agr}} || \text{pk}_N = (k_{\text{enc}_1}, ..., k_{\text{enc}_{i-1}}, k_{\text{enc}_i}, k_{\text{enc}_{i+l_{\text{pk}_N}}})$$

Part of pk_N^{Agr} is explicitly stored in N's ancestors. Additionally, for each ancestor, a single nibble is implicitly derived while traversing from the ancestor to its child included in the traversal path using the Index_N function defined in Definition 2.7.

DEFINITION 2.7. For $N \in \mathcal{N}_b$ and N_c child of N, we define \mathbf{Index}_N function as:

Index_N:
$$\{N_c \in \mathcal{N} | N_c \text{ is a child of } N\} \to \text{Nibbles}_1^4$$

 $N_c \mapsto i$

such that

$$k_{N_c} = k_N ||i|| \operatorname{pk}_{N_c}$$

Assuming that P_N is the path (see Definition 1.2) from the Trie root to node N, Algorithm 2.1 rigorously demonstrates how to build pk_N^{Agr} while traversing P_N .

Algorithm 2.1. Aggregate-Key $(P_N := (\text{TrieRoot} = N_1, ..., N_j = N))$

- 1: $\operatorname{pk}_{N}^{\operatorname{Agr}} \leftarrow \phi$
- $2: i \leftarrow 1$
- 3: while $(N_i \neq N)$
- 4: $\operatorname{pk}_{N}^{\operatorname{Agr}} \leftarrow \operatorname{pk}_{N}^{\operatorname{Agr}} || \operatorname{pk}_{N_{i}}$
- 5: $\operatorname{pk}_{N}^{\operatorname{Agr}} \leftarrow \operatorname{pk}_{N}^{\operatorname{Agr}} || \operatorname{Index}_{N_{i}}(N_{i+1})$
- 6: $i \leftarrow i + 1$
- 7: $\operatorname{pk}_{N}^{\operatorname{Agr}} \leftarrow \operatorname{pk}_{N}^{\operatorname{Agr}} || \operatorname{pk}_{N_{i}}$
- 8: **return** pk_N^{Agr}

Definition 2.8. A node $N \in \mathcal{N}$ stores the **node value**, v_N , which consists of the following concatenated data:

Formally noted as:

$$v_N := \text{Head}_N || \text{Enc}_{\text{HE}}(pk_N) || \text{sv}_N$$

where Head_N , pk_N , $\operatorname{Enc}_{\operatorname{nibbles}}$ and sv_N are defined in Definitions 2.9,2.6, B.9 and 2.11, respectively.

DEFINITION 2.9. The **node header** of node N, Head_N, consists of $l+1 \ge 1$ bytes $\operatorname{Head}_{N,1}, ..., \operatorname{Head}_{N,l+1}$ such that:

14 State Specification

Node Type pk length	pk length extra byte 1	pk key length extra byte 2	${\bf pk}{\bf length}{\bf extra}{\bf byte}l$
$\operatorname{Head}_{N,1}^{6-7} \operatorname{Head}_{N,1}^{0-5}$	$\mathrm{Head}_{N,2}$		Head _{$N,l+1$}

In which $\operatorname{Head}_{N,1}^{6-7}$, the two most significant bits of the first byte of Head_N are determined as follows:

$$\operatorname{Head}_{N,1}^{6-7} := \left\{ \begin{array}{ll} 00 & \operatorname{Special\,case} \\ 01 & \operatorname{Leaf\,Node} \\ 10 & \operatorname{Branch\,Node\,with} k_N \notin \mathcal{K} \\ 11 & \operatorname{Branch\,Node\,with} k_N \in \mathcal{K} \end{array} \right.$$

where K is defined in Definition 2.1.

 $\operatorname{Head}_{N.1}^{0-5}$, the 6 least significant bits of the first byte of Head_N are defined to be:

$$\operatorname{Head}_{N,1}^{0-5} := \begin{cases} \|pk_N\|_{\text{nib}} & \|pk_N\|_{\text{nib}} < 63\\ 63 & \|pk_N\|_{\text{nib}} \ge 63 \end{cases}$$

In which $\|\mathbf{pk_N}\|_{\mathbf{nib}}$ is the length of $\mathbf{pk_N}$ in number nibbles. $\mathrm{Head}_{N,2},...,\mathrm{Head}_{N,l+1}$ bytes are determined by Algorithm 2.2.

ALGORITHM 2.2. PARTIAL-KEY-LENGTH-ENCODING $(\text{Head}_{N,1}^{6-7}, \text{pk}_N)$

```
if \|\mathbf{p} \overline{\mathbf{k}_N}\|_{\text{nib}} \geqslant 2^{16}
  2:
                    return Error
        \operatorname{Head}_{N,1} \leftarrow 64 \times \operatorname{Head}_{N,1}^{6-7}
           if \|pk_N\|_{nib} < 63
                     \operatorname{Head}_{N,1} \leftarrow \operatorname{Head}_{N,1} + \|\operatorname{pk}_N\|_{\operatorname{nib}}
  5:
                     return Head_N
  6:
          \operatorname{Head}_{N,1} \leftarrow \operatorname{Head}_{N,1} + 63
          l \leftarrow \|\mathbf{pk}_N\|_{\mathrm{nib}} - 63
  9:
          i \leftarrow 2
           while (l > 255)
10:
                     \text{Head}_{N,i} \leftarrow 255
11:
                    l \leftarrow l - 255
12:
13:
                     i \leftarrow i + 1
          \text{Head}_{N,i} \leftarrow l
14:
           return Head_N
```

2.1.4. Merkle Proof

To prove the consistency of the state storage across the network and its modifications both efficiently and effectively, the Trie implements a Merkle tree structure. The hash value corresponding to each node needs to be computed rigorously to make the inter-implementation data integrity possible.

The Merkle value of each node should depend on the Merkle value of all its children as well as on its corresponding data in the state storage. This recursive dependancy is encompassed into the subvalue part of the node value which recursively depends on the Merkle value of its children.

We use the auxiliary function introduced in Definition 2.10 to encode and decode information stored in a branch node.

DEFINITION 2.10. Suppose $N_b, N_c \in \mathcal{N}$ and N_c is a child of N_b . We define where bit b_i : =1 if N has a child with partial key i, therefore we define **ChildrenBitmap** functions as follows:

$$\begin{split} \text{ChildrenBitmap:} & \quad \mathcal{N}_b \rightarrow \mathbb{B}_2 \\ & \quad N \mapsto (b_{15},...,b_8,b_7,...b_0)_2 \\ b_i := \left\{ \begin{array}{ll} 1 & \exists N_c \in \mathcal{N}: k_{N_c} = k_{N_b} ||i|| \mathrm{pk}_{N_c} \\ 0 & otherwise \end{array} \right. \end{split}$$

where

Definition 2.11. For a given node N, the **subvalue** of N, formally referred to as sv_N , is determined as follows: in a case which:

$$\begin{aligned} & \text{Sv}_N := \\ & \left\{ \begin{array}{l} \text{Enc}_{\text{SC}}(\text{StoredValue}(k_N)) & \textit{N is a leaf node} \\ \text{ChildrenBitmap}(N) \| \text{Enc}_{\text{SC}}(H(N_{C_1})) \dots \text{Enc}_{\text{SC}}(H(N_{C_n})) || \text{Enc}_{\text{SC}}(\text{StoredValue}(k_N)) & \textit{N is a branch node} \\ \end{array} \right. \end{aligned}$$

Where $N_{C_1} ... N_{C_n}$ with $n \leq 16$ are the children nodes of the branch node N and Enc_{SC}, StoredValue, H, and ChildrenBitmap(N) are defined in Definitions B.1,2.1, 2.12 and 2.10 respectively.

The Trie deviates from a traditional Merkle tree where node value, v_N (see Definition 2.8) is presented instead of its hash if it occupies less space than its hash.

DEFINITION 2.12. For a given node N, the **Merkle value** of N, denoted by H(N) is defined as follows:

$$H \colon \mathbb{B} \to \mathbb{B}_{32}$$

$$H(N) \colon \begin{cases} v_N & \|v_N\| < 32 \\ \text{Blake} 2b(v_N) & \|v_N\| \geqslant 32 \end{cases}$$

Where v_N is the node value of N defined in Definition 2.8 and $0_{32-\|v_N\|}$ an all zero byte array of length $32-\|v_N\|$. The **Merkle hash** of the Trie is defined as:

Where R is the root of the Trie.

CHAPTER 3

STATE TRANSITION

Like any transaction-based transition system, Polkadot state changes via an executing ordered set of instructions. These instructions are known as *extrinsics*. In Polkadot, the execution logic of the state-transition function is encapsulated in Runtime as defined in Definition 1.1. Runtime is presented as a Wasm blob in(if?) ordered be easily upgradable. Nonetheless, the Polkadot Runtime Environment needs to be in constant interaction with Runtime. The detail of such interaction is further described in Section 3.1.

In Section 3.2, we specify the procedure of the process where the extrinsics are submitted, pre-processed and validated by Runtime and queued to be applied to the current state.

Polkadot, likewise most prominent distributed ledger systems that make state replication feasible, journals and batches a series of extrinsics together in a structure knows as a block before propagating to the other nodes. The specification of the Polkadot block as well the process of verifying its validity are both explained in Section 3.3.

3.1. Interactions with Runtime

Runtime as defined in Definition • is the code implementing the logic of the chain. This code is decoupled from the Polkadot RE to make the Runtime easily upgradable without the need to upgrade the Polkadot RE itself. The general procedure to interact with Runtime is described in Algorithm 3.1.

ALGORITHM 3.1. INTERACT-WITH-RUNTIME(F: the runtime entry, $H_b(B)$: Block hash indicating the state at the end of B, $A_1, A_2, ..., A_n$: arguments to be passed to the runtime entry)

- 1: $S_B \leftarrow \text{STORAGE-AT-STATE}(H_b(B))$
- 2: $A \leftarrow \operatorname{Enc}_{\operatorname{SC}}((A_1, ..., A_n))$
- 3: Call-Runtime-Entry($R_B, \mathcal{RE}_B, F, A, A_{len}$)

In this section, we describe the details upon which the Polkadot RE is interacting with the Runtime. In particular, STORAGE-AT-STATE and CALL-RUNTIME-ENTRY procedures called in Algorithm 3.1 are explained in Notation 3.2 and Definition? respectively. R_B is the Runtime code loaded from S_B , as described in Notation 3.1, and $\mathcal{R}\mathcal{E}_B$ is the Polkadot RE API, as described in Notation F.1.

3.1.1. Loading the Runtime Code

Polkadot RE expects to receive the code for the Runtime of the chain as a compiled WebAssembly (Wasm) Blob. The current runtime is stored in the state database under the key represented as a byte array:

$$b := 3A,63,6F,64,65$$

18 State Transition

which is the byte array of ASCII representation of string ":code" (see Section D). For any call to the Runtime, Polkadot RE makes sure that it has the Runtime corresponding to the state in which the entry has been called. This is, in part, because the calls to Runtime have potentially the ability to change the Runtime code and hence Runtime code is state sensitive. Accordingly, we introduce the following notation to refer to the Runtime code at a specific state:

NOTATION 3.1. By R_B , we refer to the Runtime code stored in the state storage whose state is set at the end of the execution of block B.

The initial runtime code of the chain is embedded as an extrinsics into the chain initialization JSON file and is submitted to Polkadot RE (see Section C).

Subsequent calls to the runtime have the ability to call the storage API (see Section?) to insert a new Wasm blob into runtime storage slot to upgrade the runtime.

3.1.2. Code Executor

Polkadot RE provides a Wasm Virtual Machine (VM) to run the Runtime. The Wasm VM exposes the Polkadot RE API to the Runtime, which, on its turn, executes a call to the Runtime entries stored in the Wasm module. This part of the Runtime environment is referred to as the *Executor*.

Definition 3.2 introduces the notation for calling the runtime entry which is used whenever an algorithm of Polkadot RE needs to access the runtime.

NOTATION 3.2. By

CALL-RUNTIME-ENTRY
$$(R, \mathcal{RE}, Runtime-Entry, A, A_{len})$$

we refer to the task using the executor to invoke the Runtime-Entry while passing an $A_1, ..., A_n$ argument to it and using the encoding described in Section ?.

In this section, we specify the general setup for an Executor call into the Runtime. In Section G we specify the parameters and the return values of each Runtime entry separately.

3.1.2.1. Access to Runtime API

When Polkadot RE calls a Runtime entry it should make sure Runtime has access to the all Polkadot Runtime API functions described in Appendix?. This can be done for example by loading another Wasm module alongside the runtime which imports these functions from Polkadot RE as host functions.

3.1.2.2. Sending Arguments to Runtime

In general, all data exchanged between Polkadot RE and the Runtime is encoded using SCALE codec described in Section B.1. As a Wasm function, all runtime entries have the following identical signatures:

```
(func $runtime_entry (param $data i32) (param $len i32) (result i64))
```

In each invocation of a Runtime entry, the argument(s) which are supposed to be sent to the entry, need to be encoded using SCALE codec into a byte array B using the procedure defined in Definition B.1.

3.2 Extrinsics 19

The Executor then needs to retrieve the Wam memory buffer of the Runtime Wasm module and extend it to fit the size of the byte array. Afterwards, it needs to copy the byte array B value in the correct offset of the extended buffer. Finally, when the Wasm method runtime_entry, corresponding to the entry is invoked, two UINT32 integers are sent to the method as arguments. The first argument data is set to the offset where the byte array B is stored in the Wasm the extended shared memory buffer. The second argument len sets the length of the data stored in B., and the second one is the size of B.

3.1.2.3. The Return Value from a Runtime Entry

The value which is returned from the invocation is an i64 integer, representing two consecutive i32 integers in which the least significant one indicates the pointer to the offset of the result returned by the entry encoded in SCALE codec in the memory buffer. The most significant one provides the size of the blob.

In the case that the runtime entry is returning a boolean value, then the SCALEd (boolean) value returns in the least significant byte and all other bytes are set to zero.

3.2. EXTRINSICS

The block body consists of an array of extrinsics. Nonetheless, Polkadot RE does not specify or limit the internals of each extrinsics. From Polkadot RE point of view, each extrinsics is simply a SCALE-encoded byte array (see Definition B.1).

3.2.1. Preliminaries

DEFINITION 3.3. Account key (sk^a, pk^a) is a pair of Ristretto SR25519 used to sign extrinsics among other accounts and blance-related functions.

3.2.2. Extrinsics Submission

Extrinsic submission is made by sending a *Transactions* network message. The structure of this message is specified in Section E.1.5. Upon receiving a Transactions message, Polkadot RE decodes the transaction and calls validate_transaction runtime function, defined in Section ?G.2.7, to check the validity of the extrinsic. If validate_transaction considers the submitted extrinsics as a valid one, Polkadot RE makes the extrinsics available for the consensus engine for inclusion in future blocks.

3.2.3. Transaction Queue

A Block producer node should listen to all transaction messages. This is because the transactions are submitted to the node through the *transactions* network message specified in Section E.1.5. Upon receiving a transactions message, Polkadot RE separates the submitted transactions in the transactions message into individual extrinsics and passes them to the Runtime by executing Algorithm 3.2 to validate and store them for inclusion into future blocks. To that aim, Polkodot RE should keep a *transaction pool* and a *transaction queue* defined as follows:

DEFINITION 3.4. The **Transaction Queue** of a block producer node, formally referred to as TQ is a data structure which stores the transactions ready to be included in a block sorted according to their priorities. The **Transaction Pool**, formally referred to as TP, is a hash table in which Polkadot RE keeps the list of all valid transactions not in the transaction queue.

20 State Transition

Algorithm 3.2 updates the transaction pool and the transaction queue according to the received message:

ALGORITHM 3.2. VALIDATE-EXTRINSICS-AND-STORE(M_T : Transaction Message)

```
1:
      L \leftarrow \mathrm{Dec}_{\mathrm{SC}}(M_T)
      for T in L such that E \notin TQ and E \notin TP:
           B_d \leftarrow \text{HEAD}(\text{Longest-Chain}((BT)))
 3:
 4:
           N \leftarrow H_n(B_d)
 5:
           R \leftarrow \text{CALL-RUNTIME-ENTRY}(\texttt{TaggedTransactionQueue\_validate\_transaction}, N, T)
 6:
           if R indicates E is Valid:
                 if Requires(R)⊂
 7:
                    \bigcup_{\forall T \in (TO)} Provided-Tags(T) \cup \bigcup_{i < d, \forall T, T \in B_i} Provided-Tags(T):
                      INSERT-AT(TQ, T, Requires(R), Priority(R))
 8:
 9:
                 else
                      Add-To(TP,T)
10:
                 MAINTAIN-TRANSACTION-POOL
11:
12:
                 if Propagate(R)=True:
                      Propagate(T)
13:
```

In which

- Longest-Chain is defined in Definition 1.14.
- TaggedTransactionQueue_validate_transaction is a Runtime entry specified in Section G.2.7 and Requires(R), Priority(R) and Propagate(R) refer to the corresponding fields in the tuple returned by the entry when it deems that T is valid.
- Provided-Tags(T) is the list of tags that transaction T provides. Polkadot RE needs to keep track of tags that transaction T provides as well as requires after validating it.
- INSERT-AT(TQ, T, Requires(R), Priority(R)) places T into TQ approperietly such that the transactions providing the tags which T requires or have higher priority than T are ahead of T.
- Maintain-Transaction-Pool is described in Algorithm 3.3.
- Propagate T include T in the next transactions message sent to all peers of Polkadot RE node.

Algorithm 3.3. Maintain-Transaction-Pool

[This is scaning the pool for ready transactions and moving them to the TQ and dropping transactions which are not valid]

3.3. STATE REPLICATION

Polkadot nodes replicate each other's state by syncing the history of the extrinsics. This, however, is only practical if a large set of transactions are batched and synced at the time. The structure in which the transactions are journaled and propagated is known as a block (of extrinsics).

3.3 State Replication 21

3.3.1. Block Format

In Polkadot RE, a block is made of two main parts, namely the *block header* and the *list of extrinsics*. The Extrinsics represent the generalization of the concept of transaction, containing any set of data that is external to the system, and which the underlying chain wishes to validate and keep track of.

3.3.1.1. Block Header

The block header is designed to be minimalistic in order to boost the efficiency of the light clients. It is defined formally as follows:

DEFINITION 3.5. The header of block B, Head(B) is a 5-tuple containing the following elements:

- parent_hash: is the 32-byte Blake2b hash (see Section A.2) of the header of the parent of the block indicated henceforth by $\mathbf{H}_{\mathbf{p}}$.
- **number:** formally indicated as H_i is an integer, which represents the index of the current block in the chain. It is equal to the number of the ancestor blocks. The genesis block has number 0.
- $state_root$: formally indicated as H_r is the root of the Merkle trie, whose leaves implement the storage for the system.
- extrinsics_root: is the field which is reserved for the Runtime to validate the integrity of the extrinsics composing the block body. For example, it can hold the root hash of the Merkle trie which stores an ordered list of the extrinsics being validated in this block. The extrinsics_root is set by the runtime and its value is opaque to Polkadot RE. This element is formally referred to as H_e .
- **digest:** this field is used to store any chain-specific auxiliary data, which could help the light clients interact with the block without the need of accessing the full storage. Polkadot RE does not impose any limitation or specification for this field. Essentially, it can be a byte array of any length. This field is indicated as $\mathbf{H_d}$

DEFINITION 3.6. The Block Header Hash of Block B, $H_h(B)$, is the hash of the header of block B encoded by simple codec:"

$$H_h(B) := \text{Blake}2b(\text{Enc}_{SC}(\text{Head}(B)))$$

3.3.1.2. Justified Block Header

The Justified Block Header is provided by the consensus engine and presented to the Polkadot RE, for the block to be appended to the blockchain. It contains the following parts:

- block header the complete block header as defined in Section 3.3.1.1 and denoted by Head(B).
- **justification**: as defined by the consensus specification indicated by Just(B) [link this to its definition from consensus].
- **authority lds**: This is the list of the Ids of authorities, which have voted for the block to be stored and is formally referred to as A(B). An authority Id is 32bit.

3.3.1.3. Block Inherent Data

Block inherent data represent the totality of extrinsics included in each block. In general, these data are collected or generated by Polkadot RE and handed to Runtime for inclusion in the block. Table 3.1 lists these inherent data, their identifiers, and types.

22 State Transition

Identifier Ty	pe Des	scription
timstap0 u6	4 Uni	ix epoch time in number of seconds
babeslot u6	4 Bal	pe Slot Number ^{5.3}

Table 3.1. List of inherent data

DEFINITION 3.7. The function BLOCK-INHERENTS-DATA (B_n) return the inherent data defined in Table 3.1 corresponding to Block B as a SCALE encoded dictionary as defined in Definition B.5.

3.3.1.4. Block Body

The Block Body consists of array extrinsics each encoded as a byte array. The internal of extrinsics is completely opaque to Polkadot RE. As such, it forms the point of Polkadot RE, and is simply a SCALE encoded array of byte arrays. Formally:

Definition 3.8. The body of Block B represented as Body(B) is defined to be

$$Body(B) := Enc_{SC}(E_1, ..., E_n)$$

Where each $E_i \in \mathbb{B}$ is a SCALE encoded extrinsic.

3.3.2. Block Submission

Block validation is the process by which the client asserts that a block is fit to be added to the blockchain. This means that the block is consistent with the world state and transitions from the state of the system to a new valid state.

Blocks can be handed to the Polkadot RE both from the network stack for example by means of Block response network message (see Section E.1.3) and from the consensus engine.

3.3.3. Block Validation

Both the Runtime and the Polkadot RE need to work together to assure block validity. A block is deemed valid if the block author had the authorship right for the slot during which the slot was built as well as if the transactions in the block constitute a valid transition of states. The former criterion is validated by Polkadot RE according to the block production consensus protocol. The latter can be verified by Polkadot RE invoking execute_block entry into the Runtime as a part of the validation process.

Polkadot RE implements the following procedure to assure the validity of the block:

ALGORITHM 3.4. IMPORT-AND-VALIDATE-BLOCK(B, Just(B))

- 1: **if** $\operatorname{Just}(B) \neq \emptyset$
- 2: Verify-Block-Justification(B, Just(B))
- 3: **if** B **is** Finalized **and** P(B) **is not** Finalized
- 4: MARK-AS-FINAL(P(B))
- 5: **if** $H_p(B) \notin PBT$
- 6: return
- 7: Verify-Authorship-Right(Head(B))
- 8: $S \leftarrow \text{Call-Runtime-Entry}(\text{Core_execute_block}, B)$

3.3 State Replication 23

9: Update-World-State(S)

For the definition of the finality and the finalized block see Section 5.2. PBT is the pruned block tree defined in Definition 1.11. Verify-Authorship-Right is part of the block production consensus protocol and is described in Algorithm 5.5.

X

CHAPTER 4

NETWORK PROTOCOL

Warning 4.1. Polkadot network protocol is work-in-progress. The API specification and usage may change in future.

This chapter offers a high-level description of the network protocol based on [Tec19]. Polkadot network protocol relies on libp2p. Specifically, the following libp2p modules are being used in the Polkadot Networking protocol:

- mplex.
- yamux
- secio
- noise
- kad (kademlia)
- identity
- ping

For more detailed specification of these modules and the Peer-to-Peer layer see libp2p specification document [lab19].

4.1. Network Interactions Node Identities and Addresses

×

Similar to other decentralized networks, each Polkadot RE node possesses a network private key and a network public key representing an ED25519 key pair [LJ17].

[SPEC: local node's keypair must be passed as part of the network configuration.]

DEFINITION 4.2. **Peer Identity**, formally noted by P_{id} is derived from the node's public key as follows: [SPEC: How to derive P_{id}] and uniquely identifies a node on the network.

Because the $P_{\rm id}$ is derived from the node's public key, running two or more instances of Polkadot network using the same network key is contrary to the Polkadot protocol.

All network communications between nodes on the network use encryption derived from both sides' keys. [SPEC: p2p key derivation]

4.2. DISCOVERY MECHANISMS

In order for a Polkadot node to join a peer-to-peer network, it has to know a list of Polkadot nodes that already take part in the network. This process of building such a list is referred to as *Discovery*. Each element of this list is a pair consisting of the peer's node identities and their addresses.

26 Network Protocol

[SPEC: Node address]

Polkadot discovery is done through the following mechanisms:

• Bootstrap nodes: These are hard-coded node identities and addresses passed alongside with the network configuration.

- mDNS, performing a UDP broadcast on the local network. Nodes that listen may respond with their identity as described in the mDNS section of [lab19]. (Note: mDNS can be disabled in the network configuration.)
- Kademlia random walk. Once connected to a peer node, a Polkadot node can perform a random Kademlia 'FIND_NODE' requests for the nodes [which nodes?] to respond by propagating their view of the network.

4.3. Transport Protocol

A Polkadot node can establish a connection with nodes in its peer list. All the connections must always use encryption and multiplexing. While some nodes' addresses (eg. addresses using '/quic') already imply the encryption and/or multiplexing to use, for others the "multistream-select" protocol is used in order to negotiate an encryption layer and/or a multiplexing layer.

The following transport protocol is supported by a Polkadot node:

- TCP/IP for addresses of the form '/ip4/1.2.3.4/tcp/5'. Once the TCP connection is open, an encryption and a multiplexing layers are negotiated on top.
- WebSockets for addresses of the form '/ip4/1.2.3.4/tcp/5/ws'. A TC/IP connection is open and the WebSockets protocol is negotiated on top. Communications then happen inside WebSockets data frames. Encryption and multiplexing are additionally negotiated again inside this channel.
- DNS for addresses of the form '/dns4/example.com/tcp/5' or '/dns4/example.com/tcp/5/ws'. A node's address can contain a domain name.

4.3.1. Encryption

The following encryption protocols from libp2p are supported by Polkadot protocol:

- * Secio: A TLS-1.2-like protocol but without certificates [lab19]. Support for secio will likely to be deprecated in the future.
- * Noise: Noise is a framework for crypto protocols based on the Diffie-Hellman key agreement [Per18]. Support for noise is experimental and details may change in the future.

4.3.2. Multiplexing

The following multiplexing protocols are supported:

- Mplex: Support for mplex will be deprecated in the future.
- Yamux.

4.4 Substreams 27

4.4. SUBSTREAMS

Once a connection has been established between two nodes and is able to use multiplexing, substreams can be opened. When a substream is open, the *multistream-select* protocol is used to negotiate which protocol to use on that given substream.

4.4.1. Periodic Ephemeral Substreams

A Polkadot RE node should open several substreams. In particular, it should periodically open ephemeral substreams in order to:

- ping the remote peer and check whether the connection is still alive. Failure for the remote peer to reply leads to a disconnection. This uses the libp2p ping protocol specified in [lab19].
- ask information from the remote. This is the *identity* protocol specified in [lab19].
- send Kademlia random walk queries. Each Kademlia query is done in a new separate substreams. This uses the libp2p *Kademlia* protocol specified in [lab19].

4.4.2. Polkadot Communication Substream

For the purposes of communicating Polkadot messages, the dailer of the connection opens a unique substream. Optionally, the node can keep a unique substream alive for this purpose. The name of the protocol negotiated is based on the *protocol ID* passed as part of the network configuration. This protocol ID should be unique for each chain and prevents nodes from different chains to connect to each other.

The structure of SCALE encoded messages sent over the unique Polkadot communication substream is described in Appendix E.

Once the substream is open, the first step is an exchange of a *status* message from both sides described in Section ?.

Communications within this substream include:

- Syncing. Blocks are announced and requested from other nodes.
- Gossiping. Used by various subprotocols such as GRANDPA.
- Polkadot Network Specialization: [spec this protocol for polkadot].

CHAPTER 5

CONSENSUS

Consensus in Polkadot RE is achieved during the execution of two different procedures. The first procedure is block production and the second is finality. Polkadot RE must run these procedures, if and only if it is running on a validator node.

5.1. BLOCK PRODUCTION

Polkadot RE uses BABE protocol [Gro19] for block production designed based on Ouroboros praos [DGKR18]. BABE execution happens in sequential non-overlapping phases known as an *epoch*. Each epoch on its turn is divided into a predefined number of slots. All slots in each epoch are sequentially indexed starting from 0. At the beginning of each epoch, the BABE node needs to run Algorithm 5.1 to find out in which slots it should produce a block and gossip to the other block producers. In turn, the block producer node should keep a copy of the block tree and grow it as it receives valid blocks from other block producers. A block producer prunes the tree in parallel using Algorithm?

5.1.1. Preliminaries

DEFINITION 5.1. A **block producer**, noted by \mathcal{P}_j , is a node running Polkadot RE which is authorized to keep a transaction queue and which gets a turn in producing blocks.

DEFINITION 5.2. Block authoring session key pair $(\mathbf{sk}_j^s, \mathbf{pk}_j^s)$ is an SR25519 key pair which the block producer \mathcal{P}_j signs by their account key (see Definition 3.3) and is used to sign the produced block as well as to compute its lottery values in Algorithm 5.1.

DEFINITION 5.3. A block production **epoch**, formally referred to as \mathcal{E} is a period with pre-known starting time and fixed length during which the set of block producers stays constant. Epochs are indexed sequentially, and we refer to the n^{th} epoch since genesis by \mathcal{E}_n . Each epoch is divided into equal length periods known as block production **slots**, sequentially indexed in each epoch. The index of each slot is called **slot number**. Each slot is awarded to a subset of block producers during which they are allowed to generate a block.

NOTATION 5.4. We refer to the number of slots in epoch \mathcal{E}_n by sc_n . sc_n is set to the duration field in the returned data from the call of the Runtime entry BabeApi_epoch (see G.2.5) at the beginning of each epoch. For a given block B, we use the notation \mathbf{s}_B to refer to the slot during which B has been produced. Conversely, for slot s, \mathcal{B}_s is the set of Blocks generated at slot s.

Definition 5.5 provides an iterator over the blocks produced during an specific epoch.

30 Consensus

DEFINITION 5.5. By SubChain(\mathcal{E}_n) for epoch \mathcal{E}_n , we refer to the path graph of BT which contains all the blocks generated during the slots of epoch \mathcal{E}_n . When there is more than one block generated at a slot, we choose the one which is also on LONGEST-CHAIN(BT).

5.1.2. Block Production Lottery

DEFINITION 5.6. Winning threshold denoted by τ is the threshold which is used alongside with the result of Algorithm 5.1 to decide if a block producer is the winner of a specific slot. τ is set to result of call into BabeApi_slot_winning_threshold runtime entry.

A block producer aiming to produce a block during \mathcal{E}_n should run Algorithm 5.1 to identify the slots it is awarded. These are the slots during which the block producer is allowed to build a block. The sk is the block producer lottery secret key and n is the index of epoch for whose slots the block producer is running the lottery.

ALGORITHM 5.1. BLOCK-PRODUCTION-LOTTERY(sk: session secret key of the producer, n: epoch index)

```
1: r \leftarrow \text{Epoch-Randomness}(n)
```

2: **for** i := 1 **to** sc_n

3: $(d, \pi) \leftarrow VRF(r, i, sk)$

4: $A[i] \leftarrow (d, \pi)$

5: return A

For any slot i in epoch n where $d < \tau$, the block producer is required to produce a block. For the definitions of EPOCH-RANDOMNESS and VRF functions, see Algorithm 5.4 and Section A.4 respectively.

5.1.3. Slot Number Calculation

It is essential for a block producer to calculate and validate the slot number at a certain point in time. Slots are dividing the time continuum in an overlapping interval. At a given time, the block producer should be able to determine the set of slots which can be associated to a valid block generated at that time. We formalize the notion of validity in the following definitions:

DEFINITION 5.7. The **slot tail**, formally referred to by SITI represents the number of on-chain blocks that are used to estimate the slot time of a given slot. This number is set to be 1200.

Algorithm 5.2 determines the slot time for a future slot based on the *block arrival time* associated with blocks in the slot tail defined in Definition 5.8.

DEFINITION 5.8. The **block arrival time** of block B for node j formally represented by \mathbf{T}_{B}^{j} is the local time of node j when node j has received the block B for the first time. If the node j itself is the producer of B, T_{B}^{j} is set equal to the time that the block is produced. The index j in T_{B}^{j} notation may be dropped and B's arrival time is referred to by T_{B} when there is no ambiguity about the underlying node.

In addition to the arrival time of block B, the block producer also needs to know how many slots have passed since the arrival of B. This value is formalized in Definition 5.9.

5.1 Block Production 31

DEFINITION 5.9. Let s_i and s_j be two slots belonging to epochs \mathcal{E}_k and \mathcal{E}_l . By Slot-Offset (s_i, s_j) we refer to the function whose value is equal to the number of slots between s_i and s_j (counting s_j) on time continuum. As such, we have Slot-Offset $(s_i, s_i) = 0$.

ALGORITHM 5.2. SLOT-TIME(s: the slot number of the slot whose time needs to be determined)

```
1: T_s \leftarrow \{\}
```

2: $B_d \leftarrow \text{DEEPEST-LEAF}(BT)$

3: for B_i in SubChain $(B_{H_n(B_d)-\text{SITL}}, B_d)$

4: $s_t^{B_i} \leftarrow T_{B_i} + \text{Slot-Offset}(s_{B_i}, s) \times \mathcal{T}$

5: $T_s \leftarrow T_s \cup s_t^{B_i}$

6: **return** Median (T_s)

5.1.4. Block Production

At each epoch, each block producer should run Algorithm 5.3 to produce blocks during the slots it has been awarded during that epoch. The produced blocks need to be broadcasted alongside with the *babe header* defined in Definition 5.10.

DEFINITION 5.10. The **Babe Header** of block B, referred to formally by $H_{Babe}(B)$ is a tuple that consists of the following components:

$$(\pi, d, j, s, w)$$

in which:

 π, d : are the results of the block lottervrf output, vrfy for slot s.

j: is the SR25519 session public key associated with the block producer.

s: is the slot at which the block is produced.

w reserved

The block producer includes $H_{\text{Babe}}(B)$ as a log in $H_d(B)$ and sign Head(B) as defined in Definition?

DEFINITION 5.11. The Block Signature noted by S_B is computed as $\operatorname{Sig}_{SR25519,sk_3^s}(\operatorname{Enc}_{SC}(\operatorname{Black}2s(\operatorname{Head}(B))))$

ALGORITHM 5.3. INVOKE-BLOCK-AUTHORING(sk, pk, n, BT: Current Block Tree)

```
1: A \leftarrow \text{Block-production-lottery}(\text{sk}, n)
```

2: for $s \leftarrow 1$ to sc_n

3: Wait(until Slot-Time(s))

4: $(d,\pi) \leftarrow A[s]$

5: if $d < \tau$

6: $C_{\text{Best}} \leftarrow \text{Longest-Chain(BT)}$

7: $B_s \leftarrow \text{Build-Block}(C_{\text{Best}})$

8: Broadcast-Block $(B_s, H_{Babe}(B_s))$

32 Consensus

5.1.5. Epoch Randomness

At the end of epoch \mathcal{E}_n , each block producer is able to compute the randomness seed it needs in order to participate in the block production lottery in epoch \mathcal{E}_{n+2} . The computation of the seed is described in Algorithm 5.4 which uses the concept of epoch subchain described in Definition 5.5.

Algorithm 5.4. Epoch-Randomness(n > 2: epoch index)

```
1: \rho \leftarrow \phi
```

2: for B in SubChain(\mathcal{E}_{n-2})

3: $\rho \leftarrow \rho || d_B$

4: **return** Blake2b(EPOCH-RANDOMNESS $(n-1)||n||\rho$)

In which value d_B is the VRF output computed for slot s_B by running Algorithm 5.1.

5.1.6. Verifying Authorship Right

Definition 5.12. Seal D_s [define seal]

When a Polkadot node receives a produced block, it needs to verify if the block producer was entitled to produce the block in the given slot by running Algorithm 5.5 where:

X

- T_B is B's arrival time defined in Definition 5.8.
- $H_d(B)$ is the digest sub-component of Head(B) defined in Definition 3.5.
- Authority Directory \mathcal{E}_c is the set of Authority ID for block producers of epoch \mathcal{E}_c .
- VERIFY-SLOT-WINNER is defined in Algorithm 5.6.

ALGORITHM 5.5. VERIFY-AUTHORSHIP-RIGHT (Head_s(B): The header of the block being verified)

```
1: s \leftarrow \text{Slot-Number-At-Given-Time}(T_B)
```

- 2: $\mathcal{E}_c \leftarrow \text{Current-Epoch}()$
- 3: $(D_1, ..., D_{\operatorname{length}(H_d(B))}) \leftarrow H_d(B)$
- 4: $D_s \leftarrow D_{\text{length}(H_d(B))}$
- 5: $H_d(B) \leftarrow (D_1, ..., D_{\text{length}(H_d(B))-1})$ //remove the seal from the digest
- 6: $(id, Sig_B) \leftarrow Dec_{SC}(D_s)$
- 7: **if** $id \neq SEAL-ID$
- 8: **error** "Seal missing"
- 9: AuthorID \leftarrow AuthorityDirectory $\mathcal{E}_c[H_{\text{BABE}}(B).\text{SingerIndex}]$
- 10: VERIFY-SIGNATURE(AuthorID, $H_h(B)$, Sig_B)
- 11: **if** $\exists B' \in BT: H_h(B) \neq H_h(B)$ **and** $s_B = s_B'$ **and** SignerIndex_B = SignerIndex_{B'}
- 12: **error** "Block producer is equivocating"
- 13: Verify-Slot-Winner($(d_B, \pi_B), s$, AuthorID)

5.1 Block Production 33

Algorithm 5.6 is run as a part of the verification process, when a node is importing a block, in which:

- EPOCH-RANDOMNESS is defined in Algorithm 5.4.
- $H_{\text{BABE}}(B)$ is the BABE header defined in Definition 5.10.
- VERIFY-VRF is described in Section A.4.
- τ is the winning threshold defined in 5.6.

ALGORITHM 5.6. VERIFY-SLOT-WINNER(B: the block whose winning status to be verified)

```
1: \mathcal{E}_c \leftarrow \text{Current-Epoch}
```

- 2: $\rho \leftarrow \text{Epoch-Randomness}(c)$
- 3: Verify-VRF(ρ , $H_{\text{BABE}}(B)$. (d_B, π_B) , $H_{\text{BABE}}(B)$.s, c)
- 4: **if** $d_B \geqslant \tau$
- 5: **error** "Block producer is not a winner of the slot"

```
(d_B, \pi_B): Block Lottery Result for Block B, s_n: the slot number,
```

n: Epoch index

AuthorID: The public session key of the block producer

5.1.7. Blocks Building Process

The blocks building process is triggered by Algorithm 5.3 of the consensus engine which runs Alogrithm 5.7.

ALGORITHM 5.7. BUILD-BLOCK(C_{Best} : The chain where at its head, the block to be constructed, s: Slot number)

```
1: P_B \leftarrow \text{HEAD}(C_{\text{Best}})
```

- 2: $H_h(P_B) \leftarrow \text{CALL-RUNTIME-ENTRY}(block_hash_from_id, H_i(P_B))$
- 3: $\operatorname{Head}(B) \leftarrow (H_p \leftarrow H_h(P_B), H_i \leftarrow H_i(P_B) + 1, H_r \leftarrow \phi, H_e \leftarrow \phi, H_d \leftarrow \phi)$
- 4: CALL-RUNTIME-ENTRY(initialze_block, Head(B))
- 5: CALL-RUNTIME-ENTRY(inherent_extrinsics, BLOCK-INHERENTS-DATA)
- 6: for E in Inherents-Queue
- 7: $R \leftarrow \text{Call-Runtime-Entry}(\text{apply_extrinsic}, E)$
- 8: while not BLOCK-IS-FULL(R) and not END-OF-SLOT(S)
- 9: $E \leftarrow \text{Next-Ready-Extrinsic}()$
- 10: $R \leftarrow \text{Call-Runtime-Entry}(\text{apply_extrinsics}, E)$
- 11: **if not** BLOCK-Is-FULL(R)
- 12: DROP(READY-EXTRINSIC-QUEUE, E)
- 13: $\text{Head}(B) \leftarrow \text{Call-Runtime-Entry}(\text{finalize_block}, E)$

34 Consensus

Head(B) is defined in Definition 3.5. BLOCK-INHERENTS-DATA, INHERENTS-QUEUE, BLOCK-IS-FULL and NEXT-READY-EXTRINSIC are defined in Definition (reference) [Define these entities]

5.2. Finality

Polkadot RE uses GRANDPA Finality protocol [Ali19][Ste19] to finalize blocks. Finality is obtained by consecutive rounds of voting by validator nodes. Validators execute GRANDPA finality process in parallel to Block Production as an independent service. In this section, we describe the different functions that GRANDPA service is supposed to perform to successfully participate in the block finalization process.

×

5.2.1. Preliminaries

DEFINITION 5.13. A **GRANDPA Voter**, v, is represented by a key pair (k_v^{pr}, v_{id}) where k_v^{pr} represents its private key which is an ED25519 private key, is a node running GRANDPA protocol, and broadcasts votes to finalize blocks in a Polkadot RE - based chain. The **set of all GRANDPA voters** is indicated by \mathbb{V} . For a given block B, we have

$$\mathbb{V}_B = \mathtt{grandpa_authorities}(B)$$

where grandpa_authorities is the entry into runtime described in Section G.2.6.

Definition 5.14. **GRANDPA** state, GS, is defined as

$$GS := \{ \mathbb{V}, id_{\mathbb{V}}, r \}$$

where:

V: is the set of voters.

V_{id}: is an incremental counter tracking membership, which changes in V.

r: is the voting round number.

Now we need to define how Polkadot RE counts the number of votes for block B. First a vote is defined as:

DEFINITION 5.15. A GRANDPA vote or simply a vote for block B is an ordered pair defined as

$$V(B) := (H_h(B), H_i(B))$$

where $H_h(B)$ and $H_i(B)$ are the block hash and the block number defined in Definitions 3.5 and 3.6 respectively.

DEFINITION 5.16. Voters engage in a maximum of two sub-rounds of voting for each round r. The first sub-round is called **pre-vote** and the second sub-round is called **pre-commit**.

By $V_v^{r,pv}$ and $V_v^{r,pc}$ we refer to the vote cast by voter v in round r (for block B) during the pre-vote and the pre-commit sub-round respectively.

The GRANDPA protocol dictates how an honest voter should vote in each sub-round, which is described in Algorithm ?5.9. After defining what constitues a vote in GRANDPA, we define how GRANDPA counts votes.

DEFINITION 5.17. Voter v equivocates if they broadcast two or more valid votes to blocks not residing on the same branch of the block tree during one voting sub-round. In such a situation, we say that v is an equivocator and any vote $V_v^{r,\text{stage}}(B)$ cast by v in that round is an equivocatory vote and

 $\mathcal{E}^{r,\text{stage}}$

5.2 Finality 35

represents the set of all equivocators voters in sub-round "stage" of round r. When we want to refer to the number of equivocators whose equivocation has been observed by voter v we refer to it by:

$$\mathcal{E}_{\mathrm{obs}(v)}^{r,\mathrm{stage}}$$

Definition 5.18. A vote $V_v^{r,\text{stage}} = V(B)$ is invalid if

- H(B) does not correspond to a valid block;
- B is not an (eventual) descendant of a previously finalized block;
- $M_v^{r,\text{stage}}$ does not bear a valid signature;
- $id_{\mathbb{V}}$ does not match the current \mathbb{V} ;
- If $V_v^{r,\text{stage}}$ is an equivocatory vote.

DEFINITION 5.19. For validator v, the set of observed direct votes for Block B in round r, formally denoted by $\mathrm{VD}^{r,\mathrm{stage}}_{\mathrm{obs}(v)}(B)$ is equal to the union of:

• set of valid votes $V_{v_i}^{r,\text{stage}}$ cast in round r and received by v such that $V_{v_i}^{r,\text{stage}} = V(B)$.

DEFINITION 5.20. We refer to the set of total votes observed by voter v in sub-round "stage" of round r by $V_{obs(v)}^{r,stage}$.

The set of all observed votes by v in the sub-round stage of round r for block B, $V_{obs(v)}^{r,stage}(B)$ is equal to all of the observed direct votes casted for block B and all of the B's descendents defined formally as:

$$V^{r,\mathrm{stage}}_{\mathrm{obs}(v)}(B) := \bigcup_{v_i \in \mathbb{V}, B \geqslant B'} \mathrm{VD}^{r,\mathrm{stage}}_{\mathrm{obs}(v)}(B')$$

The total number of observed votes for Block B in round r is defined to be the size of that set plus the total number of equivocators voters:

$$\#V^{r, \mathrm{stage}}_{\mathrm{obs}(v)}(B) = |V^{r, \mathrm{stage}}_{\mathrm{obs}(v)}(B)| + |\mathcal{E}^{r, \mathrm{stage}}_{\mathrm{obs}(v)}|$$

Definition 5.21. The current **pre-voted** block $B_v^{r,pv}$ is the block with

$$H_n(B_v^{r, \text{pv}}) = \text{Max}(H_n(B) | \forall B : \#V_{\text{obs}(v)}^{r, \text{pv}}(B) \geqslant 2/3 | \mathbb{V} |)$$

Note that for genesis block Genesis we always have $\#V^{r,\mathrm{pv}}_{\mathrm{obs}(v)}(B) = |\mathbb{V}|$.

Finally, we define when a voter v see a round as completable, that is when they are confident that $B_v^{r,pv}$ is an upper bound for what is going to be finalised in this round.

Definition 5.22. We say that round r is completable if $|V_{\text{obs}(v)}^{r,\text{pc}}| + \mathcal{E}_{\text{obs}(v)}^{r,\text{pc}} > \frac{2}{3} \mathbb{V}$ and for all $B' > B_v^{r,\text{pv}}$:

$$|V_{\mathrm{obs}(v)}^{r,\mathrm{pc}}| - \mathcal{E}_{\mathrm{obs}(v)}^{r,\mathrm{pc}} - |V_{\mathrm{obs}(v)}^{r,\mathrm{pc}}(B')| > \frac{2}{3} |\mathbb{V}|$$

Note that in practice we only need to check the inequality for those $B' > B_v^{r, pv}$ where $|V_{obs(v)}^{r, pc}(B')| > 0$.

36 Consensus

5.2.2. Voting Messages Specification

Voting is done by means of broadcasting voting messages to the network. Validators inform their peers about the block finalized in round r by broadcasting a finalization message (see Algorithm ?5.9 for more details). These messages are specified in this section.

DEFINITION 5.23. A vote casted by voter v should be broadcasted as a **message** $M_v^{r, \text{stage}}$ to the network by voter v with the following structure:

 $M_v^{r, \text{stage}} := \text{Enc}_{\text{SC}}(r, \text{id}_{\mathbb{V}}, \text{Enc}_{\text{SC}}(\text{stage}, V_v^{r, \text{stage}}, \text{Sig}_{\text{ED25519}}(\text{Enc}_{\text{SC}}(\text{stage}, V_v^{r, \text{stage}}, r, V_{\text{id}}), v_{\text{id}})$

Where:

DEFINITION 5.24. The justification for block B in round r of GRANDPA protocol defined $J^r(B)$ is a vector of pairs of the type:

 $(V(B'), (\operatorname{Sign}_{v_i}^{r, \operatorname{pc}}(B'), v_{\operatorname{id}}))$

in which either

$$B' \geqslant B$$

or $V_{v_i}^{r,pc}(B')$ is an equivocatory vote.

In all cases, $\operatorname{Sign}_{v_i}^{r,\operatorname{pc}}(B')$ is the signature of voter v_i broadcasted during the pre-commit sub-round of round r. We say $J^r(B)$ justifies the finalization of B if the number of valid signatures in $J^r(B)$ is greater than $\frac{2}{3}|\mathbb{V}_B|$.

DEFINITION 5.25. GRANDPA finalizing message for block B in round r represented as $M_v^{r,Fin}(B)$ is a message broadcasted by voter v to the network indicating that voter v has finalized block B in round r. It has the following structure:

$$M_v^{r,\operatorname{Fin}}(B) := \operatorname{Enc}_{\operatorname{SC}}(r, V(B), J^r(B))$$

in which $J^r(B)$ in the justification defined in Definition 5.24.

5.2.3. Initiating the GRANDPA State

A validator needs to initiate its state and sync it with other validators, to be able to participate coherently in the voting process. In particular, considering that voting is happening in different rounds and each round of voting is assigned a unique sequential round number r_v , it needs to determine and set its round counter r in accordance with the current voting round r_n , which is currently undergoing in the network.

As instructed in Algorithm 5.8, whenever the membership of GRANDPA voters changes, r is set to 0 and $V_{\rm id}$ needs to be incremented.

Algorithm 5.8. Join-Leave-Grandpa-Voters (\mathcal{V})

1: $r \leftarrow 0$

2: $V_{id} \leftarrow ReadState('AUTHORITY SET KEY')$

5.2 Finality 37

- 3: $V_{id} \leftarrow V_{id} + 1$
- 4: EXECUTE-ONE-GRANDPA-ROUND(r)

5.2.4. Voting Process in Round r

For each round r, an honest voter v must participate in the voting process by following Algorithm 5.9.

Algorithm 5.9. Play-Grandpa-round(r)

```
1: t_{r,v} \leftarrow \text{Time}
```

2: $primary \leftarrow Derive-Primary$

3: **if** v = primary

4: Broadcast($M_v^{r-1,\text{Fin}}$ (Best-Final-Candidate(r-1)))

5: Receive-Messages(until Time $\geqslant t_{r,v} + 2 \times T$ or r is completable)

6: $L \leftarrow \text{Best-Final-Candidate}(r-1)$

7: if Received $(M_{v_{\text{primary}}}^{r,\text{pv}}(B))$ and $B_{v}^{r,\text{pv}} \geqslant B > L$

8: $N \leftarrow B$

9: **else**

10: $N \leftarrow B': H_n(B') = \max \{H_n(B'): B' > L\}$

11: BROADCAST $(M_n^{r,pv}(N))$

12: Receive-Messages(until $B_v^{r,pv} \ge L$ and (Time $\ge t_{r,v} + 4 \times T$ or r is completable))

13: Broadcast $(M_v^{r,pc}(B_v^{r,pv}))$

14: ATTEMPT-TO-FINALIZE-ROUND(r)

15: Receive-Messages(until r is completable)

16: PLAY-GRANDPA-ROUND(r+1)

The condition of *completablitiy* is defined in Definition 5.22. Best-Final-Candidate function is explained in Algorithm 5.10 and Attempt-To-Finalize-Round(r) is described in Algorithm 5.11.

ALGORITHM 5.10. BEST-FINAL-CANDIDATE(r)

```
1: C \leftarrow \{B'|B' \leqslant B_v^{r,pv}: |V_v^{r,pc}| - \#V_v^{r,pc}(B') \leqslant 1/3|V|\}
```

2: if $C = \phi$

3: return ϕ

4: **else**

5: $\operatorname{\mathbf{return}} E \in \mathcal{C}: H_n(E) = \max \{ H_n(B'): B' \in \mathcal{C} \}$

Algorithm 5.11. Attempt-To-Finalize-Round(r)

- 1: $L \leftarrow \text{Last-Finalized-Block}$
- 2: $E \leftarrow \text{Best-Final-Candidate}(r)$

38 Consensus

```
3: if E \geqslant L and V_{\mathrm{obs}(v)}^{r,\mathrm{pc}}(E) > 2/3 |\mathbb{V}|

4: Last-Finalized-Block—E

5: if M_v^{r,\mathrm{Fin}}(E) \notin \mathrm{Received}-Messages

6: Broadcast(M_v^{r,\mathrm{Fin}}(E))

7: return

8: schedule-call Attempt-To-Finalize-Round(r) when Receive-Messages
```

5.3. BLOCK FINALIZATION

DEFINITION 5.26. A Polkadot relay chain node n should consider block B as **finalized** if any of the following criteria holds for $B' \geqslant B$:

- $V_{\text{obs}(n)}^{r,\text{pc}}(B') > 2/3|\mathbb{V}_{B'}|.$
- it receives a $M_v^{r, \text{Fin}}(B')$ message in which $J^r(B)$ justifies the finalization (according to Definition 5.24).
- it receives a block data message for B' with Just(B') defined in Section ? which justifies the finalization.

for

- any round r if the node n is not a GRANDPA voter.
- only for rounds r for which the node n has invoked Algorithm 5.9 if n is a GRANDPA voter.

Note that all Polkadot relay chain nodes are supposed to listen to GRANDPA finalizing messages regardless if

APPENDIX A

CRYPTOGRAPHIC ALGORITHMS

A.1. HASH FUNCTIONS

A.2. BLAKE2

BLAKE2 is a collection of cryptographic hash functions known for their high speed. their design closely resembles BLAKE which has been a finalist in SHA-3 competition.

Polkadot is using Blake2b variant which is optimized for 64bit platforms. Unless otherwise specified, Blake2b hash function with 256bit output is used whenever Blake2b is invoked in this document. The detailed specification and sample implementations of all variants of Blake2 hash functions can be found in RFC 7693 [SA15].

A.3. RANDOMNESS

A.4. VRF

APPENDIX B

AUXILIARY ENCODINGS

B.1. SCALE CODEC

Polkadot RE uses Simple Concatenated Aggregate Little-Endian" (SCALE) codec to encode byte arrays as well as other data structures. SCALE provides a canonical encoding to produce consistent hash values across their implementation, including the Merkle hash proof for the State Storage.

DEFINITION B.1. The SCALE codec for Byte array A such that

$$A := b_1 b_2 \dots b_n$$

such that $n < 2^{536}$ is a byte array referred to $\text{Enc}_{SC}(A)$ and defined as:

$$\operatorname{Enc}_{\operatorname{SC}}(A) := \operatorname{Enc}_{\operatorname{SC}}^{\operatorname{Len}}(\|A\|) \|A\|$$

where Enc_{SC} is defined in Definition B.8.

Definition B.2. The **SCALE** codec for **Tuple** T such that:

$$T := (A_1, ..., A_n)$$

Where A_i 's are values of different types, is defined as:

$$\operatorname{Enc}_{\operatorname{SC}}(T) := \operatorname{Enc}_{\operatorname{SC}}(A_1) || \operatorname{Enc}_{\operatorname{SC}}(A_2) || ... || \operatorname{Enc}_{\operatorname{SC}}(A_n)$$

In case of a tuple (or struct), the knowledge of the shape of data is not encoded even though it is necessary for decoding. The decoder needs to derive that information from the context where the encoding/decoding is happenning.

DEFINITION B.3. We define a varying data type to be an ordered set of data types

$$\mathcal{T} = \{T_1, ..., T_n\}$$

A value A of varying date type is a pair $(A_{\text{Type}}, A_{\text{Value}})$ where $A_{\text{Type}} = T_i$ for some $T_i \in \mathcal{T}$ and A_{Value} is its value of type T_i . We define $idx(T_i) = i - 1$.

In particular, we define **optional type** to be $\mathcal{O} = \{\text{None}, T_2\}$ for some data type T_2 where idx(None) = 0 (None, ϕ) is the only possible value, when the data is of type None and a codec value is one byte of 0 value.

DEFINITION B.4. Scale coded for value $A = (A_{\text{Type}}, A_{\text{Value}})$ of varying data type $\mathcal{T} = \{T_1, ..., T_n\}$

$$\operatorname{Enc}_{\operatorname{SC}}(A) := \operatorname{Enc}_{\operatorname{SC}}(\operatorname{Idx}(A_{\operatorname{Type}})) || \operatorname{Enc}_{\operatorname{SC}}(A_{\operatorname{Value}})$$

Where Idx is encoded in a fixed length integer determining the type of A.

42 Auxiliary Encodings

In particular, for the optional type defined in Definition B.3, we have:

$$\operatorname{Enc}_{\operatorname{SC}}((\operatorname{None}, \phi)) := 0_{\mathbb{B}_1}$$

SCALE codec does not encode the correspondence between the value of Idx defined in Definition B.4 and the data type it represents; the decoder needs prior knowledge of such correspondence to decode the data.

DEFINITION B.5. The **SCALE** codec for sequence S such that:

$$S := A_1, ..., A_n$$

where A_i 's are values of the same type (and the decoder is unable to infer value of n from the context) is defined as:

$$\operatorname{Enc}_{\operatorname{SC}}(S) := \operatorname{Enc}_{\operatorname{SC}}^{\operatorname{Len}}(\|S\|) \operatorname{Enc}_{\operatorname{SC}}(A_1) |\operatorname{Enc}_{\operatorname{SC}}(A_2)| ... |\operatorname{Enc}_{\operatorname{SC}}(A_n)$$

where $\operatorname{Enc}^{\operatorname{Len}}_{\operatorname{SC}}$ is defined in Definition B.8. SCALE codec for dictionary or hashtable D with key-value pairs $(k_i, v_i)s$ such that:

$$D := \{(k_1, v_1), ..., (k_1, v_n)\}$$

is defined the SCALE codec of D as a sequence of key value pairs (as tuples):

$$\operatorname{Enc}_{\operatorname{SC}}(D) := \operatorname{Enc}_{\operatorname{SC}}^{\operatorname{Len}}(\|D\|) \operatorname{Enc}_{\operatorname{SC}}((k_1, v_1)) |\operatorname{Enc}_{\operatorname{SC}}((k_2, v_2))| \dots |\operatorname{Enc}_{\operatorname{SC}}((k_n, v_n))| |\operatorname{Enc}_{\operatorname{SC}}((k_n,$$

DEFINITION B.6. The SCALE codec for boolean value b defined as a byte as follows:

$$\begin{array}{cc} \operatorname{Enc}_{\operatorname{SC}} \colon \ \{\operatorname{False}, \operatorname{True}\} \to \mathbb{B}_1 \\ b \to \left\{ \begin{array}{ll} 0 & b = \operatorname{False} \\ 1 & b = \operatorname{True} \end{array} \right. \end{array}$$

DEFINITION B.7. The **SCALE** codec, **Enc**_{SC} for other types such as fixed length integers not defined here otherwise, is equal to little endian encoding of those values defined in Definition 1.7.

B.1.1. Length Encoding

SCALE Length encoding is used to encode integer numbers of variying sizes prominently in an encoding length of arrays:

DEFINITION B.8. SCALE Length Encoding, $\operatorname{Enc}_{\operatorname{SC}}^{\operatorname{Len}}$ also known as compact encoding of a non-negative integer number n is defined as follows:

$$\begin{split} \operatorname{Enc}_{\operatorname{SC}}^{\operatorname{Len}} \colon & \, \mathbb{N} \to \mathbb{B} \\ n \to b := \left\{ \begin{array}{ll} l_1 & 0 \leqslant n < 2^6 \\ i_1 \, i_2 & 2^6 \leqslant n < 2^{14} \\ j_1 \, j_2 \, j_3 & 2^{14} \leqslant n < 2^{30} \\ k_1 \, k_2 \dots k_m & 2^{30} \leqslant n \end{array} \right. \end{split}$$

B.3 Hex Encoding 43

in where the least significant bits of the first byte of byte array b are defined as follows:

$$\begin{array}{rcl}
l_1^1 l_1^0 &=& 00 \\
i_1^1 i_1^0 &=& 01 \\
j_1^1 j_1^0 &=& 10 \\
k_1^1 k_1^0 &=& 11
\end{array}$$

and the rest of the bits of b store the value of n in little-endian format in base-2 as follows:

$$\begin{vmatrix} l_1^7 \dots l_1^3 \, l_1^2 & n < 2^6 \\ i_2^7 \dots i_2^0 \, i_1^7 \dots i_1^2 & 2^6 \leqslant n < 2^{14} \\ j_4^7 \dots j_4^0 \, j_3^7 \dots j_1^7 \dots j_1^2 & 2^{14} \leqslant n < 2^{30} \\ k_2 + k_3 \, 2^8 + k_4 \, 2^{2 \cdot 8} + \dots + k_m \, 2^{(m-2)8} & 2^{30} \leqslant n \end{vmatrix} := n$$

such that:

$$k_1^7 \dots k_1^3 k_1^2 := m - 4$$

B.2. Frequently SCALED Object

In this section, we will specify the objects which are frequently used in transmitting data between PDRE, Runtime and other clients and their SCALE encodings.

B.2.1. Result

[Spec Result Object]

B.2.2. Error

[Spec Error Object]

B.3. HEX ENCODING

Practically, it is more convenient and efficient to store and process data which is stored in a byte array. On the other hand, the Trie keys are broken into 4-bits nibbles. Accordingly, we need a method to encode sequences of 4-bits nibbles into byte arrays canonically:

Definition B.9. Suppose that $PK = (k_1, ..., k_n)$ is a sequence of nibbles, then $Enc_{HE}(PK) :=$

$$\begin{cases} \text{Nibbles}_4 & \to \mathbb{B} \\ \text{PK} = (k_1, ..., k_n) & \mapsto \begin{cases} (16k_1 + k_2, ..., 16k_{2i-1} + k_{2i}) & n = 2i \\ (k_1, 16k_2 + k_3, ..., 16k_{2i} + k_{2i+1}) & n = 2i + 1 \end{cases}$$

APPENDIX C GENESIS BLOCK SPECIFICATION

APPENDIX D PREDEFINED STORAGE KEYS

APPENDIX E

NETWORK MESSAGES

In this section, we will specify various types of messages which Polkadot RE receives from the network. Furthermore, we also explain the appropriate responses to those messages.

Definition E.1. A network message is a byte array, M of length ||M|| such that:

$$\begin{array}{ll} M_1 & \operatorname{Message} \operatorname{Type} \operatorname{Indicator} \\ M_2...M_{\|M\|} & \operatorname{Enc}_{\operatorname{SC}}(\operatorname{MessageBody}) \end{array}$$

The body of each message consists of different components based on its type. The different possible message types are listed below in Table E.1. We describe the sub-components of each message type individually in Section E.1.

M_1	Message Type	Description
0	Status	E.1.1
1	Block Request	E.1.2
2 3	Block Response	E.1.3
3	Block Announce	E.1.4
4	Transactions	E.1.5

Table E.1. List of possible network message types.

E.1. Detailed Message Structure

This section disusses the detailed structure of each network message.

E.1.1. Status Message

A Status Message represented by M_S is sent after a connection with a neighbouring node is established and has the following structure:

$$M_S := \operatorname{Enc}_{SC}(v, r, N_B, \operatorname{Hash}_B, \operatorname{Hash}_G, C_S)$$

50 Network Messages

Where:

v:Protocol version32 bit integer v_{\min} :Minimum supported version32 bit integerr:Roles1 byte N_B :Best Block Number64 bit integerHash $_B$ Best block Hash \mathbb{B}_{32} Hash $_G$ Genesis Hash \mathbb{B}_{32} C_S Chain StatusByte array

In which, Role is a bitmap value whose bits represent different roles for the sender node as specified in Table E.2:

Value	Binary representation	Role
0	00000000	No network
1	00000001	Full node, does not participate in consensus
2	00000010	Light client node
4	00000100	Act as an authority

Table E.2. Node role representation in the status message.

E.1.2. Block Request Message

A Block request message, represented by $M_{\rm BR}$, is sent to request block data for a range of blocks from a peer and has the following structure:

 $M_{\rm BR} := \operatorname{Enc}_{\rm SC}(\operatorname{id}, A_B, S_B, \operatorname{Hash}_E, d, \operatorname{Max})$

where:

id: Unique request id 32 bit integer A_B : Requested data 1 byte

 S_B : Starting Block Varying { \mathbb{B}_{32} , 64bit integer}

 Hash_{E} End block Hash \mathbb{B}_{32} optional type

d Block sequence direction 1 byte

Max Maximum number of blocks to return 32 bit integer optional type

in which

 $-A_B$, the requested data, is a bitmap value, whose bits represent the part of the block data requested, as explained in Table E.3:

Value	Binary representation	Requested Attribute
	00000001	Block header
	00000010	Block Body
	00000100	Receipt
	00001000	Message queue
	00010000	Justification

Table E.3. Bit values for block attribute A_B , to indicate the requested parts of the data.

- S_B is SCALE encoded varying data type (see Definition B.4) of either \mathbb{B}_{32} representing the block hash, H_B , or 64bit integer representing the block number of the starting block of the requested range of blocks.

- Hash_E is optionally the block hash of the last block in the range.
- d is a flag; it defines the direction on the block chain where the block range should be considered (starting with the starting block), as follows

$$d = \begin{cases} 0 & \text{child to parent direction} \\ 1 & \text{parent to child direction} \end{cases}$$

Optional data type is defined in Definition B.3.

E.1.3. Block Response Message

A block response message represented by $M_{\rm BS}$ is sent in a response to a requested block message (see Section E.1.2). It has the following structure:

$$M_{\rm BS} := \operatorname{Enc}_{\rm SC}(\operatorname{id}, D)$$

where:

id: Unique id of the requested response was made for 32 bit integer

D: Block data for the requested sequence of Block Array of block data

In which block data is defined in Definition E.2.

DEFINITION E.2. Block Data is defined as the following tuple: Block Data definition should go to block format section

$$(H_B, \text{Header}_B, \text{Body}, \text{Receipt}, \text{MessageQueue}, \text{Justification})$$

Whose elements, with the exception of H_B , are all of the following optional type (see Definition B.3) and are defined as follows:

 H_B : Block header hash \mathbb{B}_{32}

Header_B: Block header 5-tuple (Definition 3.5)

Body Array of extrinsics Array of Byte arrays (Section 3.2)

Receipt Block Receipt Byte array
Message Queue Block message queue Byte array
Justification Block Justification Byte array

E.1.4. Block Announce Message

A block announce message represented by $M_{\rm BA}$ is sent when a node becomes aware of a new complete block on the network and has the following structure:

$$M_{\text{BA}} := \text{Enc}_{\text{SC}}(\text{Header}_B)$$

Where:

Header_B: Header of new block B 5-tuple header (Definition 3.5)

E.1.5. Transactions

The transactions Message is represented by M_T and is defined as follows:

$$M_T := \operatorname{Enc}_{\operatorname{SC}}(C_1, ..., C_n)$$

52 Network Messages

in which:

$$C_i := \operatorname{Enc}_{\operatorname{SC}}(E_i)$$

Where each E_i is a byte array and represents a sepearate extrinsic. Polkadot RE is indifferent about the content of an extrinsic and treats it as a blob of data.

E.1.6. Consensus Message

A consensus message represented by M_C is sent to communicate messages related to consensus process:

$$M_C := \operatorname{Enc}_{\operatorname{SC}}(E_{\operatorname{id}}, D)$$

Where:

 $E_{\rm id}$: The consensus engine unique identifier \mathbb{B}_4 D Consensus message payload \mathbb{B}

in which

$$E_{\mathrm{id}} := \left\{ \begin{array}{ll} "\mathrm{BABE}" & \mathrm{For\,messages\,related\,to\,BABE\,protocol} \\ "\mathrm{FRNK}" & \mathrm{For\,messages\,related\,to\,GRANDPA\,protocol} \end{array} \right.$$

The network agent should hand over D to approperiate consensus engine which identified by $E_{\rm id}$.

APPENDIX F

RUNTIME ENVIRONMENT API

The Runtime Environment API is a set of functions that Polkadot RE exposes to Runtime to access external functions needed for various reasons, such as the Storage of the content, access and manipulation, memory allocation, and also efficiency. We introduce Notation F.1 to emphasize that the result of some of the API functions depends on the content of state storage.

NOTATION F.1. By \mathcal{RE}_B we refer to the API exposed by Polkadot RE which interact, manipulate and response based on the state storage whose state is set at the end of the execution of block B.

The functions are specified in each subsequent subsection for each category of those functions.

F.1. STORAGE

F.1.1. ext_set_storage

Sets the value of a specific key in the state storage.

Prototype:

```
(func $ext_storage
  (param $key_data i32) (param $key_len i32) (param $value_data i32)
  (param $value_len i32))
```

Arguments:

- key: a pointer indicating the buffer containing the key.
- key_len: the key length in bytes.
- value: a pointer indicating the buffer containing the value to be stored under the key.
- value_len: the length of the value buffer in bytes.

F.1.2. ext_storage_root

Retrieves the root of the state storage.

Prototype:

```
(func $ext_storage_root
  (param $result_ptr i32))
```

Arguments:

• result_ptr: a memory address pointing at a byte array which contains the root of the state storage after the function concludes.

F.1.2.1. ext_blake2_256_enumerated_trie_root

Given an array of byte arrays, it arranges them in a Merkle trie, defined in Section 2.1.4, where the key under which the values are stored is the 0-based index of that value in the array. It computes and returns the root hash of the constructed trie.

Prototype:

Arguments:

- values_data: a memory address pointing at the buffer containing the array where byte arrays are stored consecutively.
- lens_data: an array of i32 elements each stores the length of each byte array stored in value_data.
- lens_len: the number of i32 elements in lens_data.
- result: a memory address pointing at the beginning of a 32-byte byte array containing the root of the Merkle trie corresponding to elements of values_data.

F.1.3. ext_clear_prefix

Given a byte array, this function removes all storage entries whose key matches the prefix specified in the array.

Prototype:

Arguments:

- prefix_data: a memory address pointing at the buffer containing the byte array containing the prefix.
- prefix_len: the length of the byte array in number of bytes.

F.1.4. ext_clear_storage

Given a byte array, this function removes the storage entry whose key is specified in the array.

Prototype:

Arguments:

- key_data: a memory address pointing at the buffer containing the byte array containing the key value.
- key_len: the length of the byte array in number of bytes.

F.1.4.1. ext_exists_storage

Given a byte array, this function checks if the storage entry corresponding to the key specified in the array exists.

F.1 Storage 55

Prototype:

Arguments:

- key_data: a memory address pointing at the buffer containing the byte array containing the key value.
- key_len: the length of the byte array in number of bytes.
- result: An i32 integer which is equal to 1 verifies if an entry with the given key exists in the storage or 0 if the key storage does not contain an entry with the given key.

F.1.5. ext_get_allocated_storage

Given a byte array, this function allocates a large enough buffer in the memory and retrieves the value stored under the key that is specified in the array. Then, it stores it in the allocated buffer if the entry exists in the storage.

Prototype:

```
(func $get_allocated_storage
  (param $key_data i32) (param $key_len i32) (param $written_out i32) (result i32))
```

Arguments:

- key_data: a memory address pointing at the buffer containing the byte array containing the key value.
- key_len: the length of the byte array in number of bytes.
- written_out: the function stores the length of the retrieved value in number of bytes if the enty exists. If the entry does not exist, it returns $2^{32} 1$.
- result: A pointer to the buffer in which the function allocates and stores the value corresponding to the given key if such an entry exist; otherwise it is equal to 0.

F.1.6. ext_get_storage_into

Given a byte array, this function retrieves the value stored under the key specified in the array and stores a specified chunk of it in the provided buffer, if the entry exists in the storage.

Prototype:

```
(func $ext_get_storage_into
  (param $key_data i32) (param $key_len i32) (param $value_data i32)
  (param $value_len i32) (param $value_offset i32) (result i32))
```

Arguments:

- key_data: a memory address pointing at the buffer containing the byte array containing the key value.
- key_len: the length of the byte array in number of bytes.

value_data: a pointer to the buffer in which the function stores the chunk of the value it retrieves.

- value_len: the (maximum) length of the chunk in bytes the function will read of the value and will store in the value_data buffer.
- value_offset: the offset of the chunk where the function should start storing the value in the provided buffer, i.e. the number of bytes the functions should skip from the retrieved value before storing the data in the value_data in number of bytes.
- result: The number of bytes the function writes in value_data if the value exists or $2^{32}-1$ if the entry does not exist under the specified key.

F.1.7. To Be Specced

- ext_clear_child_storage
- ext_exists_child_storage
- ext_get_allocated_child_storage
- ext_get_child_storage_into
- ext_kill_child_storage
- ext_set_child_storage
- ext_storage_changes_root

F.1.8. Memory

F.1.8.1. ext_malloc

Allocates memory of a requested size in the heap.

Prototype:

```
(func $ext_malloc
  (param $size i32) (result i32))
```

Arguments:

• size: the size of the buffer to be allocated in number of bytes.

Result:

a memory address pointing at the beginning of the allocated buffer.

F.1.8.2. ext_free

Deallocates a previously allocated memory.

Prototype:

F.1 Storage 57

Arguments:

• addr: a 32bit memory address pointing at the allocated memory.

F.1.8.3. Input/Output

- ext_print_hex
- ext_print_num
- ext_print_utf8

F.1.9. Cryptograppic Auxiliary Functions

F.1.9.1. ext_blake2_256

Computes the Blake2b 256bit hash of a given byte array.

Prototype:

Arguments:

- data: a memory address pointing at the buffer containing the byte array to be hashed.
- len: the length of the byte array in bytes.
- out: a memory address pointing at the beginning of a 32-byte byte array containing the Blake2b hash of the data.

F.1.9.2. ext_keccak_256

Computes the Keccak-256 hash of a given byte array.

Prototype:

Arguments:

- data: a memory address pointing at the buffer containing the byte array to be hashed.
- len: the length of the byte array in bytes.
- out: a memory address pointing at the beginning of a 32-byte byte array contanining the Keccak-256 hash of the data.

F.1.9.3. ext_twox_128

Computes the xxHash64 algorithm (see [Col19]) twice initiated with seeds 0 and 1 and applied on a given byte array and outputs the concatenated result.

Prototype:

```
(func $ext_twox_128
```

```
(param $data i32) (param $len i32) (param $out i32))
```

Arguments:

- data: a memory address pointing at the buffer containing the byte array to be hashed.
- len: the length of the byte array in bytes.
- out: a memory address pointing at the beginning of a 16-byte byte array containing $xxhash64_0(\mathtt{data})||xxhash64_1(\mathtt{data})$ where $xxhash64_i$ is the xxhash64 function initiated with seed i as a 64bit unsigned integer.

F.1.9.4. ext_ed25519_verify

Given a message signed by the ED25519 signature algorithm alongside with its signature and the allegedly signer public key, it verifies the validity of the signature by the provided public key.

Prototype:

Arguments:

- msg_data: a pointer to the buffer containing the message body.
- msg_len: an i32 integer indicating the size of the message buffer in bytes.
- sig_data: a pointer to the 64 byte memory buffer containing the ED25519 signature corresponding to the message.
- pubkey_data: a pointer to the 32 byte buffer containing the public key and corresponding to the secret key which has signed the message.
- result: an integer value equal to 0 indicating the validity of the signature or a nonzero value otherwise.

F.1.9.5. ext_sr25519_verify

Given a message signed by the SR25519 signature algorithm alongside with its signature and the allegedly signer public key, it verifies the validity of the signature by the provided public key.

Prototype:

Arguments:

- msg_data: a pointer to the buffer containing the message body.
- msg_len: an i32 integer indicating the size of the message buffer in bytes.
- sig_data: a pointer to the 64 byte memory buffer containing the SR25519 signature corresponding to the message.

F.1 Storage 59

• pubkey_data: a pointer to the 32 byte buffer containing the public key and corresponding to the secret key which has signed the message.

• result: an integer value equal to 0 indicating the validity of the signature or a nonzero value otherwise.

F.1.9.6. To be Specced

• ext_twox_256

F.1.10. Offchain Worker

X

The Offichain Workers allow the execution of long-running and possibly non-deterministic tasks (e.g. web requests, encryption/decryption and signing of data, random number generation, CPU-intensive computations, enumeration/aggregation of on-chain data, etc.) which could otherwise require longer than the block execution time. Offichain Workers have their own execution environment. This separation of concerns is to make sure that the block production is not impacted by the long-running tasks.

[Describe how the results are going to impact the blocks etc]

As Offichain Workers run on their own execution environment they have access to their separate storage. There are two different types of storage available as defined in Definitions F.2 and F.3.

DEFINITION F.2. **Persistent storage** is non-revertible and not fork-aware. It means that any value set by the offchain worker is persisted even if that block (at which the worker is called) is reverted as non-canonical (meaning that the block was surpassed by a longer chain). The value is available for the worker that is re-run at the new (different block with the same block number) and future blocks. This storage can be used by offchain workers to handle forks and coordinate offchain workers running on different forks.

DEFINITION F.3. Local storage is revertible and fork-aware. It means that any value set by the offchain worker triggered at a certain block is reverted if that block is reverted as non-canonical. The value is NOT available for the worker that is re-run at the next or any future blocks.

DEFINITION F.4. HTTP status codes that can get returned by certain Offichain HTTP functions.

- 0: the specified request identifier is invalid.
- 10: the deadline for the started request was reached.
- 20: an error has occurred during the request, e.g. a timeout or the remote server has closed the connection.

 On returning this error code, the request is considered destroyed and must be reconstructed again.
- 100..999: the request has finished with the given HTTP status code.

F.1.10.1. ext_is_validator

Returns if the local node is a potential validator. Even if this function returns 1, it does not mean that any keys are configured and that the validator is registered in the chain.

Prototype:

Arguments:

• result: an i32 integer which is equal to 1 if the local node is a potential validator or a equal to 0 if it is not.

F.1.10.2. ext_submit_transaction

Given an extrinsic as a SCALE encoded byte array, the system decodes the byte array and submits the extrinsic in the inherent pool as an extrinsic to be included in the next produced block.

Prototype:

Arguments:

- data: a pointer to the buffer containing the byte array storing the encoded extrinsic.
- len: an i32 integer indicating the size of the encoded extrinsic.
- result: ×an integer value equal to 0 indicates that the extrinsic is successfully added to the pool or a nonzero value otherwise.

X

F.1.10.3. ext_network_state

Returns opaque information about the local node's network state.

Prototype:

Arguments:

- written_out: a pointer to the 4-byte buffer where the size of the opaque network state gets written to.
- result: a pointer to the buffer containing the SCALE encoded network state. [Spec the detail of the the result this requires a deeper look since it includes datastructures from libp2p-dev]

F.1.10.4. ext_timestamp

Returns current timestamp.

Prototype:

Arguments:

• result: an i64 integer indicating the current UNIX timestamp as defined in Definition 1.10.

F.1 Storage 61

F.1.10.5. ext_sleep_until

Pause the execution until 'deadline' is reached.

Prototype:

Arguments:

• deadline: an i64 integer specifying the UNIX timestamp as defined in Definition 1.10.

F.1.10.6. ext_random_seed

Generates a random seed. This is a truly random non deterministic seed generated by the host environment.

Prototype:

Arguments:

• seed_data: a memory address pointing at the beginning of a 32-byte byte array containing the generated seed.

F.1.10.7. ext_local_storage_set

Sets a value in the local storage. This storage is not part of the consensus, it's only accessible by the offchain worker tasks running on the same machine and is persisted between runs.

Prototype:

Arguments:

- kind: an i32 integer indicating the storage kind. A value equal to 1 is used for a persistent storage as defined in Definition F.2 and a value equal to 2 for local storage as defined in Definition F.3.
- key: a pointer to the buffer containing the key.
- key_len: an i32 integer indicating the size of the key.
- value: a pointer to the buffer containg the value.
- value_len: an i32 integer indicating the size of the value.

F.1.10.8. ext_local_storage_compare_and_set

Sets a new value in the local storage if the condition matches the current value.

Prototype:

Arguments:

- kind: an i32 integer indicating the storage kind. A value equal to 1 is used for a persistent storage as defined in Definition F.2 and a value equal to 2 for local storage as defined in Definition F.3.
- key: a pointer to the buffer containing the key.
- key_len: an i32 integer indicating the size of the key.
- old_value: a pointer to the buffer containing the current value.
- old_value_len: an i32 integer indicating the size of the current value.
- new_value: a pointer to the buffer containing the new value.
- new_value_len: an i32 integer indicating the size of the new value.
- result: an i32 integer equal to 0 if the new value has been set or a value equal to 1 if otherwise.

F.1.10.9. ext_local_storage_get

Gets a value from the local storage.

Prototype:

Arguments:

- kind: an i32 integer indicating the storage kind. A value equal to 1 is used for a persistent storage as defined in Definition F.2 and a value equal to 2 for local storage as defined in Definition F.3.
- key: a pointer to the buffer containing the key.
- key_len: an i32 integer indicating the size of the key.
- value_len: an i32 integer indicating the size of the value.
- result: a pointer to the buffer in which the function allocates and stores the value corresponding to the given key if such an entry exist; otherwise it is equal to 0.

F.1.10.10. ext_http_request_start

Initiates a http request given by the HTTP method and the URL. Returns the id of a newly started request.

Prototype:

F.1 Storage 63

Arguments:

- method: a pointer to the buffer containing the key.
- method_len: an i32 integer indicating the size of the method.
- url: a pointer to the buffer containing the url.
- url_len: an i32 integer indicating the size of the url.
- meta: a future-reserved field containing additional, SCALE encoded parameters.
- meta_len: an i32 integer indicating the size of the parameters.
- result: an i32 integer indicating the ID of the newly started request.

F.1.10.11. ext_http_request_add_header

Append header to the request. Returns an error if the request identifier is invalid, http_response_wait has already been called on the specified request identifier, the deadline is reached or an I/O error has happened (e.g. the remote has closed the connection).

Prototype:

Arguments:

- request_id: an i32 integer indicating the ID of the started request.
- name: a pointer to the buffer containing the header name.
- name_len: an i32 integer indicating the size of the header name.
- value: a pointer to the buffer containing the header value.
- value_len: an i32 integer indicating the size of the header value.
- result: an i32 integer where the value equal to 0 indicates if the header has been set or a value equal to 1 if otherwise.

F.1.10.12. ext_http_request_write_body

Writes a chunk of the request body. Writing an empty chunk finalises the request. Returns a non-zero value in case the deadline is reached or the chunk could not be written.

Prototype:

Arguments:

• request_id: an i32 integer indicating the ID of the started request.

- chunk: a pointer to the buffer containing the chunk.
- chunk_len: an i32 integer indicating the size of the chunk.
- deadline: an i64 integer specifying the UNIX timestamp as defined in Definition 1.10. Passing '0' will block indefinitely.
- result: an i32 integer where the value equal to 0 indicates if the header has been set or a non-zero value if otherwise.

F.1.10.13. ext_http_response_wait

Blocks and waits for the responses for given requests. Returns an array of request statuses (the size is the same as number of IDs).

Prototype:

Arguments:

- ids: a pointer to the buffer containing the started IDs.
- ids_len: an i32 integer indicating the size of IDs.
- statuses: a pointer to the buffer where the request statuses get written to as defined in Definition F.4. The length is the same as the length of ids.
- deadline: an i64 integer indicating the UNIX timestamp as defined in Definition 1.10. Passing '0' as deadline will block indefinitely.

F.1.10.14. ext_http_response_headers

Read all response headers. Returns a vector of key/value pairs. Response headers must be read before the response body.

Prototype:

Arguments:

- request_id: an i32 integer indicating the ID of the started request.
- written_out: a pointer to the buffer where the size of the response headers gets written to.
- result: a pointer to the buffer containing the response headers.

F.1.10.15. ext_http_response_read_body

Reads a chunk of body response to the given buffer. Returns the number of bytes written or an error in case a deadline is reached or the server closed the connection. If '0' is returned it means that the response has been fully consumed and the request_id is now invalid. This implies that response headers must be read before draining the body.

F.1 Storage 65

Prototype:

Arguments:

- request_id: an i32 integer indicating the ID of the started request.
- buffer: a pointer to the buffer where the body gets written to.
- buffer_len: an i32 integer indicating the size of the buffer.
- deadline: an i64 integer indicating the UNIX timestamp as defined in Definition 1.10. Passing '0' will block indefinitely.
- result: an i32 integer where the value equal to 0 indicateds a fully consumed response or a non-zero value if otherwise.

F.1.11. Sandboxing

F.1.11.1. To be Specced

- ext_sandbox_instance_teardown
- ext_sandbox_instantiate
- ext_sandbox_invoke
- ext_sandbox_memory_get
- ext_sandbox_memory_new
- ext_sandbox_memory_set
- ext_sandbox_memory_teardown

F.1.12. Auxillary Debugging API

F.1.12.1. ext_print_hex

Prints out the content of the given buffer on the host's debugging console. Each byte is represented as a two-digit hexadecimal number.

Prototype:

```
(func $ext_print_hex
  (param $data i32) (parm $len i32))
```

Arguments:

- data: a pointer to the buffer containing the data that needs to be printed.
- len: an i32 integer indicating the size of the buffer containing the data in bytes.

F.1.12.2. ext_print_utf8

Prints out the content of the given buffer on the host's debugging console. The buffer content is interpreted as a UTF-8 string if it represents a valid UTF-8 string, otherwise does nothing and returns.

Prototype:o

```
(func $ext_print_utf8
  (param $utf8_data i32) (param $utf8_len i32))
```

Arguments:

- utf8_data: a pointer to the buffer containing the utf8-encoded string to be printed.
- utf8_len: an i32 integer indicating the size of the buffer containing the UTF-8 string in bytes.

F.1.13. Misc

F.1.13.1. To be Specced

• ext_chain_id

F.1.14. Block Production

F.2. VALIDATION

APPENDIX G

RUNTIME ENTRIES

G.1. LIST OF RUNTIME ENTRIES

Polkadot RE assumes that at least the following functions are implemented in the Runtime Wasm blob and have been exported as shown in Snippet G.1:

```
(export "Core_version" (func $Core_version))
(export "Core_execute_block" (func $Core_execute_block))
(export "Core_initialize_block" (func $Core_initialize_block))
(export "Metadata_metadata" (func $Metadata_metadata))
(export "BlockBuilder_apply_extrinsic" (func $BlockBuilder_apply_extrinsic))
(export "BlockBuilder_finalize_block" (func $BlockBuilder_finalize_block))
(export "BlockBuilder_inherent_extrinsics"
        (func $BlockBuilder_inherent_extrinsics))
(export "BlockBuilder_check_inherents" (func $BlockBuilder_check_inherents))
(export "BlockBuilder_random_seed" (func $BlockBuilder_random_seed))
(export "TaggedTransactionQueue_validate_transaction"
        (func $TaggedTransactionQueue_validate_transaction))
(export "OffchainWorkerApi_offchain_worker"
        (func $0ffchainWorkerApi_offchain_worker))
(export "ParachainHost_validators" (func $ParachainHost_validators))
(export "ParachainHost_duty_roster" (func $ParachainHost_duty_roster))
(export "ParachainHost_active_parachains"
        (func $ParachainHost_active_parachains))
(export "ParachainHost_parachain_status" (func $ParachainHost_parachain_status))
(export "ParachainHost_parachain_code" (func $ParachainHost_parachain_code))
(export "ParachainHost_ingress" (func $ParachainHost_ingress))
(export "GrandpaApi_grandpa_pending_change"
        (func $GrandpaApi_grandpa_pending_change))
(export "GrandpaApi_grandpa_forced_change"
        (func $GrandpaApi_grandpa_forced_change))
(export "GrandpaApi_grandpa_authorities" (func $GrandpaApi_grandpa_authorities))
(export "BabeApi_startup_data" (func $BabeApi_startup_data))
(export "BabeApi_epoch" (func $BabeApi_epoch))
(export "SessionKeys_generate_session_keys"
       (func $SessionKeys_generate_session_keys))
```

 ${\bf Snippet~G.1.~Snippet~to~export~entries~into~tho~Wasm~runtime~module.}$

68 Runtime Entries

The following sections describe the standard based on which Polkadot RE communicates with each runtime entry.

G.2. ARGUMENT SPECIFICATION

As a wasm functions, all runtime entries have the following prototype signature:

```
(func $generic_runtime_entry
```

```
(param $data i32) (parm $len i32) (reslut i64))
```

where data points to the SCALE encoded paramaters sent to the function and len is the length of the data. result can similarly either point to the SCALE encoded data the function returns or represent a boolean value (See Sections 3.1.2.2 and 3.1.2.3).

In this section, we describe the function of each of the entries alongside with the details of the SCALE encoded arguments and the return values for each one of these enteries.

G.2.1. Core_version

This entry receives no argument; it returns the version data encoded in ABI format described in Section 3.1.2.3 containing the following information:

Name	Type	Description
spec_name	String	Runtime identifier
impl_name	String	the name of the implementation (e.g. $C++$)
authoring_version	UINT32	the version of the authorship interface
spec_version	UINT32	the version of the Runtime specification
impl_version	UINT32	the version of the Runtime implementation
apis	ApisVec	List of supported AP

Table G.1. Detail of the version data type returns from runtime version function.

G.2.2. Core_execute_block

This entry is responsible for executing all extrinsics in the block and reporting back if the block was successfully executed.

Arguments:

• The entry accepts the block data defined in Definition E.2 as the only argument.

Return:

A Boolean value indicates if the execution was successful.

G.2.3. Core_initialise_block

[Spec initialize block]

G.2.4. hash_and_length

An auxiliarry function which returns hash and encoding length of an extrinsics.

Arguments:

• A SCALE encoded blob of an extrinsic.

Return:

Pair of Blake2Hash of the blob as element of \mathbb{B}_{32} and its length as 64 bit integer.

G.2.5. BabeApi_epoch

This entry is called to obtain the current configuration of BABE consensus protocol.

Arguments:

• $H_n(B)$: the block number at whose final state the epoch configuration should be obtained.

Return:

A tuple

$$(\mathcal{E}_n, s_0^n, \mathrm{sc}_n, A, \rho, \mathrm{Sec})$$

where:

 \mathcal{E}_n : epoch index (see Definition 5.3) 64-bit integer s_0^n : The index of the starting slot of \mathcal{E}_n 64-bit integer sc_n: Slot count of \mathcal{E}_n (see Definition 5.3) 1 byte

A: The list of authorities and their weights Array of (P_A, W_A)

 ρ Randomness used in \mathcal{E}_n (see Section 5.1.5) \mathbb{B}_{32} Sec To be specced Boolean

in which:

 P_A : The public key of authority A \mathbb{B}_{32}

 W_A : The weight of the authority A 64 bit integer

G.2.6. Grandpa_authorities

This entry is to report the set of GRANDPA voters at a given block. It receives block_id as an argument; it returns an array of authority_id's.

G.2.7. TaggedTransactionQueue_validate_transaction

This entry is invoked against extrinsics submitted through the Transaction network message E.1.5 and indicates if the submitted blob represents a valid extrinsics applied to the specified block.

Arguments:

- $H_n(B)$: the block number whose final state is where the transaction should apply the system state.
- UTX: A byte array that contains the SCALE encoded transaction.

Return:

A varying type Result object which has type of *TransactionValidity* in case no error occurs in course of its execution. TransactionValidity is of varying type described in the Table G.2:

70 Runtime Entries

Type Index	Data type	Description
0	Byte	Indicating invalid extrinsic and bearing the error code concerning
		the cause of invalidity of the transaction.
1	A Quin-tuple	Indicating whether the extrinsic is valid and providing guidance for
		Polkadot RE on how to proceed with the extrinsic (see below)
2	Byte	The Validity of the extrinsic cannot be determined

 ${\bf Table~G.2.}~{\bf Type~variation~for~the~return~value~of~TaggedTransactionQueue_transaction_validity.}$

In which the quintuple of type for valid extrinsics consists of the following parts:

(priority, requires, provides, longevity, propagate)

Name	Description	Type
Priority	Determines the ordering of two transactions that have	64bit integer
	all their dependencies (required tags) satisfied.	
Requires	List of tags specifying extrinsics which should be applied	Array of
	before the current exrinsics can be applied.	Transaction Tags
Provides	Informs Runtime of the extrinsics depending on the tags in	Array of
	the list that can be applied after current extrinsics are being applied.	Transaction Tags
	Describes the minimum number of blocks for the validity to be correct	
Longevity	After this period, the transaction should be removed from the	64 bit integer
	pool or revalidated.	
Propagate	A flag indicating if the transaction should be propagated to	Boolean
	other peers.	

Table G.3. The quintuple provided by TaggedTransactionQueue_transaction_validity in the case the transaction is judged to be valid.

Note that if *Propagate* is set to false the transaction will still be considered for including in blocks that are authored on the current node, but will never be sent to other peers.
